I certify that $I$ have read this thesis and that in my opinion it is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

Martin E. Hellman

I certify that $I$ have read this thesis and that in my opinion it is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

I certify that $I$ have read this thesis and that in my opinion it is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

Approved for the University Committee on Graduate Studies:

It is the author's great pleasure to acknowledge the aid, the help, the assistance, and the support of: my fellow graduate students, Steve Pohlig, Raynold Kahn, Dov Andleman, and Justin Reyneri; Bob Fabry and Jim Reeds on the faculty at U.C. Berkeley; the independent and imaginative Whit Diffie; the ever helpful Charlotte Coe; my fellow Berkeley students Peter Blatman, Bruce Englar, Frank Olken, and Loren Kohnfelder; the love and support of Carol Shaw; and my mother, who knew I could do it all along.

I would like to give my special thanks to Martin Hellman, whose support made it possible and who encouraged me when it counted most: when little was known and much was doubted.

Thanks are also due to the National Science Foundation for it's support of the work described in chapter's III, IV, VI, VII, VIII, IX and $X$ under grant ENG-10173; and to the U.S. Air Force Office of Scientific Research and the U.S. Army Research Office for their support of the work described in chapters II, $V$ and VII under contracts F49620-78-C-0086 and DAAG29-78-C0036.

## I. INTRODUCTION

1. Intraduction

Cryptography is a fascinating subject, even more, so today than in the past. The new and once unthinkable ideas of public key distribution and digital signatures have opened up new fields of research, and new possibilities for the marketplace. To be one of the first to venture into this virgin territory has been a great privilege.

This thesis presents the findings of work done between fall of 1974 and spring of 1979.

Chapters III and IV describing the "puzzle" methods are now primarily of pedagogicel and historical interest: they were the first break in what at that time appeared to be a smooth and solid wall.

Chapter VI, on the trapdoor knapsack, describes the second real breakthrough, (the first was the key distribution method based on exponentiation developed by Hellman) and represents work done in the summer of 1976.

Chapter $V$, on a certified digital signature, was conceived in the summer of 1977. To some extent it represents frustration over the difficulties of extracting signatures in a clean and reliable way from the trapdoor knapsack.

Chapter VII is a follow up on chapter VI. It attempts to provide reasons for believing that the trapdoor knapsack is actually secure. The author is, of course, quite convinced it is
secure; but inventors have traditionally been blind to the weaknesses and obvious faults of their cryptographic inventions. It has therefore been very encouraging to hear from others that they have failed miserably in attempts to analyze it.

Chapter IX on protocols provides insight into the problems and techniques of actually using public key systems.

Chapter VIII describes an essentially NP-complete conventional cryptosystem, a theoretical result which might provide a useful avenue for further research aimed at getting proofs of security.

Chapter $X$ describes a cryptanalytic method for breaking an apparent improvement which has been suggested to the DES. Its description of potential weakness in a particular scheme for multiple encipherment carries with it a simple moral: simple extensions or modifications to a cryptographic algorithm can have unexpected weaknesses.

## 2. Conventional Cryptography

Conventional cryptographic systems provide secrecy and authentication to information which may be overheard or modified by unauthorized third parties. This is done by enerypting (or enciphering) the plaintext $P$ with a key $K$ to produce the ciphertext $C: S_{K}(P)=C$, where $S_{K}$ denotes the enciphering function under key $K$. Only authorized users know $K$, and so only they can decipher $C$ by computing $P=S_{K}^{-1}(C)$. Although unauthorized users know $C$ and the set of functions $\left\{S_{K}\right\}$, this does not allow them either to determine $P$ or to modify $C$ to produce a $C^{\prime}$ which deciphers to a meaningful message.

The security of such systems resides entirely in the key K. All other components of the system are assumed to be public knowledge. To maintain security, the legitimate users of the system must learn $K$, while preventing others from learning it. To date, this has been done by sending $K$ to the legitimate users of the system over special physically secure communication channels, e.g., registered mail or couriers. The flow of information in a conventional cryptographic system is shown in figure 1.

PAGE 3A

## 3. Public Key Systems

The reader interested in public key cryptography is referred to [4] for an excellent tutorial overview. So that this thesis is self contained, two sections from that paper are reproduced below with only minor changes to introduce the concepts of public key systems and digital signatures.

The difficulty of distributing keys has been one of the major limitations on the use of conventional cryptographic technology. In order for the sender and receiver to make use of a physically secure chamnel such as registered mail for key distribution, they must be prepared to wait while the keys are sent, or have meḍe prior preparation for cryptographic communication.

In the military, the chain of command helps to limit the number of user-pair connections, but even there, the key distribution problem has been a major impediment to the use of cryptography. This problem will be accentuated in large commercial communication networks where the number of possible connections is $\left(n^{2}-n\right) / 2$ where $n$ is the number of users. A system with one million users has almost 500 billion possible connections, and the cost of distributing this many keys is prohibitive.

At this point we introduce a new kind of cryptographic system which simplifies the problem of key distribution. It is
possible to dispense with the secure key distribution chennel of figure 1, and communicate over the insecure channel without any prearrangement. As indicated in figure 2, two way commui-. cation is allowed between the transmitter and receiver, but the eavesdropper is passive and only listens. Systems of this type are called public key systems, in contrast to conventional systems.

The reason that keys must be so carefully protected in conventional cryptographic systems is that the enciphering and deciphering functions are inseparable. Anyone who has access to the key in order to encipher messages can also decipher messages. If the enciphering and deciphering capabilities are separated, privacy can be achieved without keeping the enciphering key secret, because it can no longer be used for deciphering.

The new systems must be designed so that it is easy to generate $a$ randon pair of inverse keys $E$, for enciphering, and D, for deciphering, and easy to operate with $E$ and $D$, but computationally infeasible to compute $D$ from $E$.

A public key cryptosystem is a pair of families $\left\{E_{K}\right\}$ and $\left\{D_{K}\right\}$ for $K$ in $\{K\}$, of algorithms representing en invertible transformation and its inverse defined such that:

1) For every $K$ in $\{K\}, D_{K}$ is the inverse of $E_{K}$. That is, $D_{K}\left(E_{K}(M)\right)=M$, for any $K$ and any $\mu$.
2) For every $K$ in $\{K\}$ and $M$ in $\{M\}$, the values $E_{K}(M)$ and

PAGE 5A
$D_{K}(M)$ are easy to compute.
3) For nearly all K in $\{\mathrm{K}\}$, any easily computed algorithm equivalent to $D_{K}$ is computationally infeasible to. derive from $E_{K}$.
4) For every $K$ in $\{K\}$, it is feasible to generate the inverse pair $E_{K}$ and $D_{K}$ from $K$.

The third property allows a user's enciphering key $\mathrm{E}_{\mathrm{K}}$ to be made public without compromising the security of his secret deciphering key $\mathrm{D}_{\mathrm{K}}$. .. The cryptographic system is therefore split into two parts, a family of enciphering transformations, and a family of deciphering transformations in such a way that given a member of one family it is infeasible to find the corresponding member of the other.

The fourth property guarantees that there is a feasible way of computing corresponding pairs of inverse transformations when no constraint is placed on whet either the enciphering or deciphering transformation is to be. In practice, the cryptoequipment must contain a true random number generator (e.g., a noisy diode) for generating $K$, together with an algorithm for generating the $E_{K}-D_{k}$ pair from $K$.

A system of this kind greatly simplifies the problem of key distribution. Each user generates a pair of inverse transformations, E and D. He keeps the deciphering transformation $D$ secret, and makes the enciphering transformation $E$ public by, for example, placing it in a public directory similar

## INTRODUCTION

```
to a phone book. Anyone can now encrypt messages and send them
to the user, but no one else can decipher messages intended for
him.
    If in addition to conditions 1) - 4) above, the set of
transformations satisfy
```

$1^{\prime \prime}$ ) For every $K$ in $\{K\}, E_{K}$ is the inverse of $D_{K}$. That is for any $K$ and any $M, E_{K} D_{K}(N)=M$.

It is possible, and often desirable, to encipher with $D$ and decipher with -E . For this reason, $\mathrm{E}_{\mathrm{K}}$ is sometimes called the public key, and $D_{K}$ the secret (or signing) key.

## 4. Digital Signatures

## A second difficulty which has limited the application of conventional cryptography is its inability to deal with the problem of dispute. Conventional authentication systems can prevent third party forgeries, but cannot settle disputes between the sender and receiver as to what message, if any, was sent.

In current commercial practice, the validity of contracts and agreements is gueranteed by bandwritten signatures. A signed contract serves as proof of an agreement which the holder can present in court if necessary, but the use of signatures requires the transmission and storage of written documents: a major barrier to more widespread use of electronic communications in business.

The essence of a signature is that although only one person can produce it, anybody can recognize it. If there is to be a purely digital replacement for this paper instrument, each user must be able to produce messages whose authenticity can be checked by anyone, but which could not have been produced by anyone else, especially the intended recipient. In a conventional system the receiver authenticates any message he receives from the sender by deciphering it in a key which the two hold in common. Because this key is held in common, however, the recelver has the ability to produce any cryptogram that
could have been produced by the sender and so cannot prove that the sender actually sent a disputed message.

Public key cryptosystems provide a direct solution to the signature problem, if they satisfy condition 11). Systems which almost satisfy $1^{1}$ ) are also usable (see chapter VI).

If user $A$ wishes to send a signed message $M$ to user $B$, he operates on it with his private key $D_{A}$ to produce the signed message $S=D_{A}(M)$. $D_{A}$ was used as $A$ 's deciphering key when privacy was desired, but is now used as his "enciphering" or "signing" key. When user $B$ receives $\&$ he can recover $M$ by operating on $S$ with A's public key $E_{A}$.

B saves $S$ as proof that user $A$ sent him the particular message $M$. Jf $A$ later disclaims having sent this message, $E$ can take $S$ to a judge who obtains $E_{A}$ and checks that $E_{A}(S)=M$ is a meaningful message with A's name at the end, the proper date and time, etc. Only user A could have generated $s$ because only he knows $D_{A}$, so $A$ will be held responsible for heving sent M.

This technique provides unforgeable, message dependent, digital signatures, but allows any eavesdropper to determine $M$ because only the public information $E_{A}$ is needed to recover $M$ from S. To obtain privacy of communication as well, $A$ can encrypt $S$ with $R^{\prime}$ s public key and send $E_{B}(S)$ instead of $S$. Only $B$ knows $D_{B}$, so only he can recover $S$ and thence $M$. $E$ still saves $S$ as proof that user $A$ sent him $N$.

Other methods of generating digital signatures which do

## INTRODUCTION

not depend on public key cryptosystems have been suggested [6], [19] and Chapter V.

> [Note: This concludes the two sections taken largely from
[4].]

## II. ONE WAY HASH FUNCTIONS

- There are many instances in which a large data field (e.g. 10,000 bits) needs to be authenticated, but only a small data field (e.g. 100 bits) can be stored or authenticated. (See, for example, chapter $V$ ). It is often required that it be infeasible to compute other large data fields with the same image under the hash function, giving rise to the need for a one way hash function.

Intuitively, a one way hash function $F$ is one which is easy to compute but difficult to invert and can mep arbitrarily large data fields onto much smaller ones. If $y=F(x)$, then given $x$ and $F$, it is easy to compute. $y$, but given $y$ and $F$ it is effectively impossible to compute $x$. More precisely:

1) $F$ can be applied to any argument of any size. $F$ applied to more than one argument (e.g. $F\left(x_{1}, x_{2}\right)$ ) is equivalent to $F$ applied to the concatenation of the arguments, i.e. $F\left(\left\langle x_{1}, x_{2}\right\rangle\right)$.
2) F always produces a fixed size output, which, for the sake of concreteness, we take to be 100 bits.
3) Given $F$ and $x$ it is easy to compute $F(x)$.
4) Given $F$ and $F(x)$, it is computationally infeasible to determine x .
5) Given $F$ and $x$, it is computationally infeasible to find an $x^{\prime} \neq x$ such that $F(x)=F\left(x^{\prime}\right)$.

The major use of one way functions is for authentication.

If a value $y$ can be authenticated, we can authenticate $x$ by computing

$$
F(x)=y
$$

and authenticating $y$.
No other input $x^{1}$ can be found (although they probably exist) which will generate $y$. A 100 bit $y$ can authenticate an arbitrarily large $x$. This property is crucial for the convenient authentication of large amounts of information. Al.though a 100 bit $y$ is plausible, selection of the size in a real system involves tradeoffs between the reduced cost and improved efficiency of a smaller size, and the improved security of a larger size.

Because $y$ is used to authenticate the corresponding $x$, it would be intolerable if someone could compute on $x^{\prime \prime}$ such that $y$ $=F(x)=F\left(x^{\prime}\right)$. The fraudulent $x^{\prime}$ could be substituted for the legitimate $x$ and would be authenticated by the same information. If $y$ is 100 bits long, an interloper must try about $2^{100}$ different values of $x^{\prime}$ before getting a value such that $F\left(x^{\prime}\right)_{f}^{\prime}=$ y. In an actual system, $F$ will be applied to many different values of $x$, producing many different values of $y$. As a consequence, trying fewer then $2^{100}$ different values of $x$ will probably yield an $x^{\prime}$ such that $F\left(x^{\prime}\right)=y$ for some already authenticated $y$. To take a concrete example, assume $F$ has been applied to $2^{40}$ different values of $x$, and produced $2^{40}$ corresponding values of $y$, each of which has been authenticated. If the $y^{\prime} s$ are 100 bits, then a random search over $2^{60}$ values of $x$ would
probably yield an $x^{\prime \prime}$ such that $y=F(x)=F\left(x^{\prime}\right)$ for some value of $y$. While this search is still difficult, it is easier than searching over $2^{100}$ different values of $x$. This demonstrates' that $y$ might have to be longer than expected in a heavily used system. Forcing an opponent to search over all $2^{100}$ different values of $x$ would be more desirable. This can usually be done by using many different functions, $F_{1}, F_{2}, \ldots$ The effect of using many different one way functions is to prevent analysis of $F$ by exhaustive techniques, because each value of $x$ is authenticated with a distinct $F_{i}$. This will significantly increase security, yet requires only minor changes in implementation.

Functions such as $F$ can be defined in terms of conventional cryptographic functions [6]. Assume we have a conventional encryption function $C(k e y, p l a i n t e x t)$ which has a"200 bit key size and encrypts 100 bit blocks of plaintext into 100 bit blocks of ciphertext. (It is a common misconception that the key can be no larger than the plaintext blocksize, but as fin example the DES can be regarded as having a 768 bit key and a 64 bit block size).

We first define $F_{0}$, which is simpler than $F$ and which satisfies properties $2,3,4$, and 5 ; but whose input $x$ is restricted to be 200 bits. We define

$$
F_{0}(x)=y=c(x, \underline{0})
$$

$F_{0}$ accepts a 200 bit input $x$ and produces a 100 bit output $y$, as desired. Furthermore, given $y$, the problem of finding an $x^{\prime}$
such that $F\left(x^{\prime}\right)=y$ is equivalent to finding a key $x^{\prime}$ such that $y=C\left(x^{1}, \underline{0}\right)$. If $C$ is a good encryption function, this is computationally infeasible.

If the input $x$ to $F$ is fewer than 200 bits, then we can "pad" $x$ by adding $0^{\prime \prime} s$ until it is exactly 200 bits, and then define $F=F_{0}$. If the input is more than 200 bits, we will break it into 100 bit pieces. Assume that

$$
\underline{x}=x_{1}, x_{2}, \ldots x_{k}
$$

and thet each $x_{1}$ is 100 bits long. Then $F$.is defined in terms of repeated applications of $F_{0} . \quad F_{0}$ is first applied to $x_{1}$ and $x_{2}$ to obtain $y_{1}=F_{0}\left(x_{1}, x_{2}\right)$. Then $y_{2}=F_{0}\left(y_{1}, x_{3}\right), y_{3}=$ $F_{0}\left(y_{2}, x_{4}\right), y_{4}=F_{0}\left(y_{3}, x_{5}\right), \ldots y_{i}=F_{0}\left(y_{i-1}, x_{i+1}\right), \ldots y_{k-1}=$ $F_{0}\left(y_{k-2}, x_{k}\right)$. $F(\underline{x})$ is defined to be $y_{k-1}$; the final $y$ in the series. If $x$ is not an exact multiple of 100 bits, then it is padded with 0 's, as above.

It is obvious that $F$ can accept arbitrarily large values for $x$. Although complexity theory has not progressed to the point where it is possible to prove that it will be computfó tionally infeasible to find any vector $x^{\prime}$ not equal., to $x$ such that $F(\underline{x})=F\left(\underline{x}^{\prime}\right)$, a plasibility argument can be made inductively that this is the case. As a basis, when $k=2$, the property holds because $F(\underline{x})=F_{0}\left(x_{1}, x_{2}\right)$, and the property holds for $F_{0}$ by assumption. We establish the case for $k=3$ by contradiction. We assume that $F\left(x_{1}, x_{2}, x_{3}\right)=F\left(x_{1}{ }^{\prime}, x_{2}{ }^{\prime}, x_{3}{ }^{\prime}\right)$ and that $x_{i} \neq x_{i}$ for some $i$ in $\{1,2,3\}$. We first note that $F\left(x_{1}, x_{2}, x_{3}\right)=F_{0}\left(y_{1}, x_{3}\right)$ by definition. If either $y_{1} \neq y_{1}^{\prime}$ or
$x_{3} \neq x_{3}{ }^{\prime}$, and $F_{0}\left(y_{1}, x_{3}\right)=F_{0}\left(y_{1}{ }^{\prime}, x_{3}{ }^{\prime}\right)$, then we have violeted assumption 5 made about $F_{0}$ : If $y_{1}=y_{1}^{\prime}$ and $x_{3}=x_{3}$, then either $x_{1} \neq x_{1}$ or $x_{2} \neq x_{2}^{\prime}$. By definition. $F_{0}\left(x_{1}, x_{2}\right)=y_{1}$, and $F_{0}\left(x_{1}{ }^{\prime}, x_{2}{ }^{\prime}\right)=y_{1}{ }^{\prime}$, so $F_{0}\left(x_{1}, x_{2}\right)=F_{0}\left(x_{1}{ }^{\prime}, x_{2}{ }^{\prime}\right)$ and again we contradict assumption 5 made about $\mathrm{F}_{0}$. This line of logic can be extended to the cases $k=3,4,5$,

This argument cannot be made fully rigorous until the properties of $F_{0}$ are mede rigorous. This must await further advances in complexity theory.
III. A PURLIC KEY CRYPTOSYSTEM BASED CN PUZZLES

This chapter describes the first public key distribution system and the first pubiic key cryptosystem, which were both based on the concept of a "puzzle".

Puzzles can be used in a variety of ways to make public key distribution systems where the effort involved to break the system grows as the square of the effort to use the system. The method described in chapter IV is not the simpiest, but was selected because it required the least memory and was deterministic. (As an interesting aside, Ron Rivest sent the euthor a letter mentioning this fact, and described a simpler system which was, in fact, the system the author originally devised.)

As originally conceived, the method wes more closely linked to the concept of a one way function and was probabilistic in nature. Pasically, it centered on the observation that if two people randomly select $n$ numbers from a space of $n^{2}$ numbers, there is a sigrificent probability that both will have selected at least one number in common. This is closely related to the "birthdey problem" [41]. Given $n$ people in a room, what is the probability that et least two of them were born on the same day? The probability becomes surprisingly high when there are more than square $\operatorname{root}(365) \equiv 20$ people in the room.

This surprising statistical result can be used for public key distribution rather easily. If $A$ and $B$ wish to agree on $a$ common key, then each selects $n$ numbers from $a$ space of $n^{2}$ numbers. The probability that they selected a common number is significant and if $A$ and $P$ can determine this common number it

## A PUBLIC KEY CRYPTOSYSTEM EPSFD ON PUZZLES

can be used as a cryptographic key in further commuications. Note that the number of possible keys is $n^{2}$, so anyone who tries to break this method must search through all $n^{2}$, rether than the $O(n)$ keys that $A$ and $E$ know.

A and $E$ determine the common number as follows: A applies a one way function $F$ to hide each of his $n$ randomly chosen numbers, and sends them to $E$. E applies $F$ to hide his randomy chosen numbers and sends the result to $A . A$ and $B$ can now sort both lists of hidden numbers, and look for a match. If A and P chanced upon the same number, then the hidden version of this number computed by $A$ and $P$ will be the same. All that $E$ knows is the hidden versions of the numbers. $E$ cen easily look through A's and E's hidden numbers and find the match, but then E must search thrcugr, all $r^{2}$ possible values to find the original velue, which is used es the key. $A$ and $P$, on the other hand, already KNOK the original values, because they generated the hidden values by applying $F$ to numbers they knew.

The next phase in the evolutionary development of the method was to create a deterministic version of the original method. This is done fairly easily. Instead of selecting $n$ numbers from $n^{2}$ possibilities completely at random, select one number randomly in the range from 1 to $n$, the second number randomly in the range from $n+1$ to $2 \cdot n$, the third number randomly in the range from $2 \cdot \mathrm{r}+1$ to $3 \cdot n$, the $i$ th number from the range $(i-1) \cdot n+1$ to $i \cdot n$, and the nth number from the range $(n-1) \cdot n+1$ to $n \cdot n$. This guarantees that there must
be one number in each of the $n$ possible ranges. By picking a randon range, and then searching sequentially through all possible numbers in that range, a "collision" must occur. In other words, A picks a single number randomly from each range, hides them, randomly permutes their order and transmits the permuted hidden values to $P$. B picks a random range, hides all $n$ numbers in that range, but does not send the resuit to $A$. Instead, E looks for a match between the hidden numbers A sent, and the hidcen numbers $E$ just generated. When $E$ finds the match, $E$ sends the hidden velue back to $A$, who compares this single hidden numier against the $n$ hidden numbers A generated. The method now deteministically achieves an $n^{2}: n$ ratio of effort (work factor). However, it still requires a great deal of memory.

The method described in chapter IV was the next evolutionary step beyond this.

The "puzzles" metrod also evolved into the first public key eryptosystem. Pasically, the enciphering end deciphering keys are just explicit tabular representations of randomiy chosen enciphering and deciphering functions. The only modification is to the enciphering key. It cannot be represented in a simple tabular formet, because this would allow it to be inverted too easily, i.e., the public enciphering key must be hard to invert, and a tabular format is not hard to invert, so the tabular formet must be extended somewhat. This is done by
enpuzzling the elexer:ss of the range.
First, we define the enpuzzlement of an argument by the function:
$P(x, n)$
where $x$ is the value to be enpuzzled, and $n$ represents the difficulty of breaking the resulting puzzle. $P(345.45)$ means that the number "2u5" can be recovered by putting in 45 units of effort (on average).

A small enciptering key; which maps pleintext 1 into ciphertext 7, pleintext 2 into ciphertext 3, ... and plaintext 8 into ciphertext 5; is shown in figure 1 , with $n=8$.

The Enciphering Key

& P(3,8) \\
& P(6,8) \\
& P(8, \varepsilon) \\
& P(1,8) \\
& P(4,8) \\
& P(2,8) \\
& P(5, \varepsilon)
\end{aligned}
$$

Figure 1

Note that it resuires $C(n)$ units of effort to compute

## A PUPLIC KEY CRYPTOSYSTEM EASED ON PUZZLES

E(plaintext) from this tabular representation, but that computing $D$ (ciphertext) requires $O\left(n^{2}\right)$.

The corresponding secret deciphering key is shown in figure 2.

## The Deciphering Key

15
$2 \quad 7$
$3 \quad 2$
$4 \quad 6$
$5 \quad 8$
63
7 1
C $\quad 4$

## Figure 2

The secret deciphering key is not enpuzzled, and so it is easy to complite $D$ (ciphertext) from it, (or to compute E(plaintext), but this is largely beside the point). Kaking the enciphering and deciphering keys can be done in $O(n)$ time, enciphering reçuires $O(n)$ time, deciphering can be done in unjt time, but breaking the system requires $O\left(n^{2}\right)$ time.

## 1. INTRODUCTION

Tinis chapter describes the first public key system ever developed. Until this system, it had been assumed thet a necessary precondition for cryptogrephically secure communicetions was the transmission of a key, by secret. means, prior to an attempt to communicate securely. The system described below, however, allows two communicants to select a key publicly, but in such a fashion that no one else can easily determine what it is.
The body of the chapter will begin with a description of a conventiona? cryptographic system, in which secure transmission of the key is reguired. It will then develop the new concept of a public key system. The implications of public key systems will then be explored in more detail, with the aid of some examples.

## 2. REVIEV

We introduce three protagonists into our paradigm: A and , the two communicants, and $E$, the enemy, who wishes to find out what A and $E$ are communicating. $A$ and $P$ have available a conventional cryptographic system for encrypting end decrypting messages that they send to each other. A, $E$, and $E$ all know the general method of encryption. A and $B$ also neve available a normil communications channel, over which they send the bulk of their messages. To allow $A$ and $P$ to communicate securely, they must load a key, which is unknown to $E$, into their cryptographic devices. The general method uses this key as a parameter, and will perform a particular trensformetion on messages for a perticuler key. Because $E$ does not know this key, he cannot perform the particular transformation, and thus cannot encrypt or decrypt messages.

A and $P$ must both know what the key is, and must insure that 5 does nct know what it is. In the traditional paradigm for eryptography, this situation comes about by the transmission of the key from $A$ to $E$ over some special end secure communications channel which we shall refer to as the key channel. E. cannot intercept messages sent on this channe], and the key is therefore safe.

The key channel is not used for normal communications because of its expense and inconvenience.

In vien of the central position that the key channel will
occupy in this chapter, it would be wise to state, somewhat more clearly, the conditions which it must satisfy. There are two such conditions.

1) E cannot modify or alter messages on the key channel, nor can he inject false or spurious messages.
2) E is unable to determine the content of any message sent over the key channel, i.e.. $E$ cannot intercept the messages.

Systems of this type are referred to as conventional cryptographic systems, and their study dates back to antiquity (See Shannon [35] for a good overview). We now make a modifjcation which had not previously been considered.

## PURLIC KEY DISTRIRUTION USING PUZZLES

## 3. THE NEW APPROACH

We modify the traditional paradigm by dropping the second restriction on the key channel, but not the first. We no longer demand that $E$ be unabie to learn what is sent on the key channel, rather, we assume that $E$ has perfect knowledge of everything that is sent over this channel [footnote page 31]. Although in some instances the key and normal channels may be one and the same, we shall treat them as logically distinct.

It is the thesis of this chapter that secure commications between $A$ and $E$ can take place under the conditions we have just described.

The reader should clearly understand that no key iurks in the background. There is no method by which $A$ and $B$ can communicate other than the normal channel and the key channel. They have made no secret preparations prior to the time that they kish to communicate securely.

We must cerefully consider what constitutes a solution. If A and $E$ eventually agree upon a key, and if the work requirec of $E$ to determine the key is much higher than the work put in by either $A$ or E to select the key, then we have a solution. Note that $E$ can determine the key used in most conventional cryptographic systems (with the exception of the one time pac) simply by trying all possible keys and seeing which one produces 2 legible message. However, the amount of work required grows exponentially compared to the amount of work put

## PUBLIC KEY DISTRIPUTION USING PUZZLES

in by $A$ or $P$. The public key solution cescribed is not exponential, but the amount of work required of $E$ to determine the key increases as the square of the amount of work put. in by A and $P$ to select the key. Methods which appear to force $E$ to put in an amount of work which grows exponentially with the amount of work $A$ and $E$ put in have been discovered since the conception of this method. While this method is therefore not es practicel, its simplicity makes it the most nearly provably secure system and the best for pedagogical purposes. It relies on little more than the existence of one wey functions.

## 4. THE METHOD

The method is based on the concept of a puzzle, that is, a. cryptogram which is meant to, be broken. To solve the puzzle, we must cryptanalyze the cryptogram. Having done this, we learn the information that was "enpuzzled", the plaintext of the cryptogram. Just as we can encrypt plaintext to produce a cryptogram, so we can enpuzzle information to produce a puzzle. A puzzle, though, is meant to be solved, while ideally, a cryptogram cannot be cryptanalyzed. To solve a puzzle, all you need do is put in the required amount of effort.

To sharpen our definition, we will consider the following method of creating puzzles. First, select a strong encryption function. he are not interested in the details of how this encryption function works: our only interest is that it does work. The reader can select any encryption function that he feels is particularly strong and effective. A concrete example might be the DES encryption function [24], which with a longer key is currently felt to be quite strong.

After selecting an encryption function, we create our puzzle by encrypting some piece of information with that function with a key chosen at random from a specified subset of the keyspace. We artificially restrict the size of the key space used with the encryption function to make the puzzle solvable. If the key is normally 122 bits, we might use on:y 30 bits and set the remaining 98 bits to 0 . While searching through $2^{128}$

## PUBLIC KEY DISTRIBUTION USING PUZZLES

possible keys is completely infeasible, searching through $2^{30}$ is tedious, but quite possible. We can control the difficulty of solving a puzzle, simply by changing the restriction on the size of the key space used. To make the puzzle harder to solve, we might select a 40 bit key, while to make it easier, we might select a 20 bit key. We assume the strength of the underlying encryption function is adequate to insure that our puzzle cen only be solved by exhaustive search through the restricted key space, and we can then adjust the size of the key space to precisely control the difficulty of solving the puzzle.

There is still one more point that must be brought out. In crydtanalyzing an encrypted message, the cryptenalyst relies on recundancy ir the message to indicate when the proper key is tried. If the information we enpuzzle is random, there will be no redundency, and thus no way of solving the puzzle. We must deliberately introduce redundancy into our puzzle, so that it can be solved. This can be done easily enough by encrypting, along witr the information, a constant that is publicly stated. When we try to decrypt the puzzle with a particular key, the recovery of this constant can be taken as evidence that we have selected the right key, and thus have solved the puzzle. The absence of the constant part in the decrypted puzzle guarantees that we have used the wrong key, and should try again. While an incorrect key can produce a false alarm, if the constant field is larger than the number of bits in the restricted key

## PUBLIC KEY DJSTPIBUTION USING PUZZLES

space, then unicity distance argumente indicate that false al arms should be rare.

With the concept of puzzle in hand, we can proceed. We let. $A$ and $E$ agree upor the value of $N$ which they wish to use. $A$ then generates $N$ puzzles, and transmits these $N$ puzzles to $P$ over the key channel. A chooses the size of the key space so that these puzzles require $O(N)$ effort to break. (That is, $A$ selects a key space of size $K \cdot N$, for a constant, K.) Each puz2]e contains, within itself, two pieces or information. Neither piece of information is readily aveilable to anyone examining the puzzle. By devoting $O(N)$ effort to solving the puz2le, it is possible to determine both these pieces of information. One piece of information is a puzzle id, which uniquely identiries each of the $N$ puzzles. The ids were assigned by $A$ at randor. The other piece of information in the puzzle is a random bit string which is the proper size for use as a true (unrestricted) key, i.e., one of the possible keys to be used ir subsequent encrypted communications. To distinguish the true keys, one for each puzzle, from the keys randomly selected from the restricted key space to create the puzzles, we will call the former "true keys", and the latter, "restricted keys". Thus, $N$ true keys are enpuzzled, and in the process of enpuzzling each true key, a restricted key is used.

When $P$ is presented with this menu of $N$ puzzles, he selects a puzzle at random and spends $O(n)$ effort to solve the puzzle. $B$ then transmits the id back to $A$ over the key chan-

## PUBLIC KEY DISTRIBUTION USING PUZZLES

nel, and uses the true key found in the puzzle as the key for further encrypted communcations over the normal channel.
$A, P$, and $E$ all know the $N$ puzzles. They also know the id, because $B$ transmitted the id over the key channel. E knows the corresponding true key, because E selected the puzzie to be solved. A knows the corresponding true key, because A knows which true key is associated with the id that $P$ sent. $E$ knows only the id, but does not know the true key. E does not know winich puzzle contains the true key thet $P$ selected, and wich $A$ and 2 are using, even thougr he knows the id. To determine winich puzzle is the correct one, he must break puzzles at ransom until he encounters the one with the correct id.

If $E$ is to determine the key which $A$ and $E$ are using, then, on an average, $E$ will have to solve $1 / 2 \mathrm{~N}$ puzzies before reaching the puzzle that $E$ solved. Each puzzle has been constructed so that it reouires $O(N)$ effort to break, so $E$ must spend, on an zverage, $O\left(N^{2}\right)$ effort to determine the key. $B$, on the other hand, need only spend $O(N)$ effort to break the one puzzle he selected, while $A$ need only spend $O(N)$ effort to -.ancfacture the I puzzles. Thus, both $A$ and $E$ will only put in $C(N)$ effort. A detailed description appears in [21].

In summery: the method Eilows the use of channels satisfyEng assumption 1, and not satisfying essumption 2, for the transmission of key information. We need only guarantee that ressages are unmodified, end we no longer require that they be urread. If the two communicarts, $A$ and $P$, put in $C(N)$ effort.

## PUSLIC KEY DISTRIRUTION USJNC PUZZLES

then the enemy. $E$, must. put in $O\left(N^{2}\right)$ effort to determine the key.

Generating the $n$ puzzles is orders of magnitude less costly than transmitting them. Creating a method in which the ratio of efforts was still $n^{2}: n$, but which did not require transmitting $C(n)$ bits would be a substantial and practical improvement. There seems no reason in principal why such an improvement should not be possible.

## PUBLIC KEY DISTRIEUTJON USING PUZZLES

## 5. FOOTNOTE

Wyner [30] introduced a different (information theoretic)approach to secure communication over an insecure channelwithout prearrangement. kyner assumes that the wiretepper $E$has inferior reception of the messages being transmitted. Bytaking advantage of this inferior reception, Wyner shows howthe wiretapper cen be completely confused. Our approach is dif-ferent and assumes that both the legitimate receiver and thewiretapper perfectly recejve whatever the transmitter sends.
## 1. Introduction

Digital signatures promise to revolutionize business by phone or other telecommunication devices [6] but use of the currently known public key cryptosystems [18], [20], [21], [31] is risky until they have been carefully certified. A signature system whose security rested solely on the security of a conventional cryptographic function would be "pre-certified" to the extent that the underiying encryption function had been certified. The delays and cost of a new certification effort would be avoided. Lamport and Diffie [6] suggested such a system, but it has severe performance drawbacks. Lipton and Matyas [17] nonetheless suggested its use as the only near term solution to a pressing problem.

This chapter describes a digital signature system which is "pre-certified" in the above sense, generates signatures of about 15 kilobits (2 kilobytes), requires a few thousand applications of the underlying encryption function per signature, and only a few kilobytes of memory. If the underlying encryption function takes 10 , microseconds to encrypt a block, generating a signature taked approximately 20 milliseconds.

The following major points are covered:
1.) A description of the Lamport-Diffie one time signa-. tore.
2.): An improved version of the Lamport-Diffie one time signature.
3.) A method of converting any one time signature into a convenient signature system.

## 2. The Lamport-Diffie One Time Signature

The Lamport-Diffie one time signature [6] is based on the concept of a one way function [7], [38]. If $y=F(x)$ is the result of applying the one way function $F$ to input $x$, then the key observation is:

The person who computed $y=F(x)$ is the only person who knows $x$. If $y$ is publicly revealed, oniy the originator of $y$ knows $x$, and can choose to reveal or conceal $x$ at his whim.

This is best clarified by an example. Suppose a person $A$ has some stock, which he can sell at any time. A dight wish to sell the stock on short notice, which means that A would like to tell his broker over the phone. The broker, E , does not wish to sell with only a phone call as authorization. To solfe this problem, $A$ computes $y=F(x)$ and gives $y$ to $B$. They agree that when $A$ wants to sell his stock he will reveal $x$ to $E$. (This agrement could bẹ formalized as a written contract [17] which includes the value of $y$ and $a$ description of $F$ but not the value of $x$. ) $E$ will then be able to prove that $A$ wanted to sell bis stock, because $B$ will be able to exhibit $x$, and demonstrate that $F(x)=y$.

If $A$ later denies having ordered $B$ to sell the stock, $R$
can show the contract and $x$ to a judge as proof that $A$, con- . trary to his statement, did order the stock sold. Both $F$ and $y$ are given in the original (written) contract, so the judge can compute $F(x)$ and verify that it equals $y$. The only person who knew $x$ was $A$, and the only way $E$ could have learned $x$ would be if $A$ had revealed $x$. Therefore, $A$ must have revealed $x$; an action which by prior agreement meant that A wanted to sell his stock.

This example illustrates a signature system which "signs" a single bit of information. Either A sold the stock, or be did not. If $A$ wanted to tell his broker to sell 10 shares of stock, then $A$ must be able to sign a several bit message. In the general Lamport-Diffie scheme, if $A$ wanted to sign a message $m$ whose size was $s$ bits, then he would precompute $F\left(x_{1}\right)=$ $y_{1}, F\left(x_{2}\right)=y_{2}, F\left(x_{3}\right)=y_{3}, \ldots F\left(x_{s}\right)=y_{s} . \quad A$ and $B$ would agree on the vector $Y=y_{1}, y_{2} \ldots y_{s}$. If the $j$ th bit of $m$ was a 1 , A would reveal $x_{j}$. If the $j \underline{\text { th }}$ bit of mas a $0, A$ would not reveal $x_{j}$. In essence, each bit of $m$ would be individualif $y^{\prime}$ signed. Arbitrary messages can be signed, one bit at a time.

In practice, long messages (greater than 100 bits) can be mapped into short messages (100 bits) by a one way function and only the short message signed. We can therefore assume, without loss of generality, that all messages are a fixed length, e.g., 100 bits.

The method as described thus far suffers from the defect that $B$ can alter $m$ by changing bits that are ${ }^{1}$ 's into $0^{\prime} s$. E
simply denies he ever received $\dot{x}_{j}$, (in spite of the fact he did). However, $0^{\prime \prime} s$ cannot be changed to $\mathbf{1 ' s}^{\prime} \mathrm{s}$. Lamport and Diffie overcame this problem by signing a new message m', which is exactly twice as long as mand is computed by concatenating m with the bitwise complement of m. That is, each bit $m_{j}$ in the originel message is represented by two bits, $m_{j}$ and the complement of $m_{j}$ in the new message $m^{\prime}$. Clearly, one or the other bit must be a 0 . To alter the message, $B$ would have to turn a 0 into a 1 , something he cannot do.

It should now be clear why this method is a "one time" signature: Each $Y=y_{1}, y_{2}, \ldots y_{2}$ can only be used to sign one message. If more than one message is to be signed, then new values $Y_{1}, Y_{2}, Y_{3}, \ldots$ are needed, a new $Y_{i}$ for each message.

One time signatures are practical between a single pair of users who are willing to exchange the large amount of data necessary but they are not practical for most applications without further refinements. If each $y_{i}$ is 100 bits long and á 100 bit one way hash function of each message, is signed, each $Y_{i}$ must be 20,000 bits. If 1000 messages are to be signed before new public authentication data is needed, over 20,000,000 bits or 2.5 megabytes must be stored as public information. Even if this is not overly burdensome when only two users, $A$ and $B$, are involved in the signature system, if $B$ had to keep 2.5 megabytes of data for 1000 other users, $E$ would have to store 2.5 gigabytes of data. While possible, this hardly seems

## A CERTIFIED DIGITAL SIGNATURE

economical. With further increases in the number of users, or . in the number of messages each user wants to be able to sign, the system becomes completely unwieldy.

How to eliminate the huge storage requirements is a major subject of this chapter.

## A CERTIFIED DIGITAL SIGNATURE

## 3. An Improved One Time Signature

This section explains. how to reduce the size of signed messages in the Lamport-Diffie method by almost a factor of 2.

As previously mentioned, the Lamport-Diffie method solves the problem that $1^{1 ' s}$ in the original message can be altered to 0's by doubling the length of the message, and signing each bit and its complement independently. In this way, changing a 1 to a 0 in the new message, $m^{\prime}$, would result in an incorrectly formatted message, which would be rejected. In essence, this represents a solution to the problem:

Create a coding scheme in which accidental or intentional conversion of 1 's to 0 's will produce an ille gal codeword.

An alternative coding method which accomplishes the same result is to append a count of the number of 0 bits in $m$ before signing. The new message, m', would be only $\log _{2} s$ bits longer than the original $s$ bit message, $m$. If any $1^{\prime \prime} s$ in $m$ were $!$
changed to $0^{\prime \prime} s\left(0^{\prime} s\right.$ cannot be changed to $1^{\prime \prime} s$ ), it would falsify the count of $0^{\prime} s$.

Notice that while it is possible to reduce the count by changing $1^{\prime \prime} s$ to $0^{\prime \prime} s$ in the count field, and while it is possible to increase the number of $0^{\prime \prime} s$ by changing $1^{\prime} s$ to $0^{1} s$ in the
message, these two "errors" cannot be made to compensate for. each other.

A smali example is in order. Assume that our messages are. e bits long, and that our count is $\log _{2} 8=3$ bits long. If our message m is
$m=11010110$
Then mi would be
$m^{\prime}=11010110,011$
(Where a comma is used to clarify the division of $m$ ' into $m$ and its 0 count.)

If the codeword 11010110,011 were changed to 01010110,011 by changing the first 1 to a 0 , then the count 011 would have to be changed to 100 because we now have $40^{\prime} s$, not 3 . Fut this requires changing a 0 to a 1 , something we cannot do. If the codeword were changed to 11010110,010 by altering the 0 count then the message would have to be changed so that it had only $20^{\prime \prime}$ instead of 3 . Again, this change is illegal because it requires changing $0^{\prime} s$ to 1 's.

This improved method is easy to implement and cuts the size of the signed message almost in half, although this is still too large for most applications; e.g.. it reduces 2.5 gigabytes to 1.25 gigabytes.

## 4. Tree Authentication

A new protocol would eliminate the large storage requirements and the need for prior arrangements. If A transmitted $\boldsymbol{Y}_{i}$ to E just before signing a message, then $B$ would not previously have had to get and keep copies of the $Y_{i}$ from A. Unfortunately, such a protocol would not work because anyone could claim to be $A$, send a false $Y_{i}$, and trick $E$ into thinking he had received a properly authorized signature when he-had received nothing of the kind. $B$ must somehow be able to confirm that he was sent the correct $Y_{i}$ and not a forgery. i

The problem is to authenticate $A^{\prime} s Y_{i}$. The simplest (but unsatisfactory) method is, as suggested above, to keep a copy of A's $Y_{i}$. In this section, we describe a method called "tree authentication" which can be used to authenticate any $Y_{i}$ of any user quickly and easily, but which requires minimal storage.

Problem Definition: Given a vector of data items $\underline{Y}=Y_{1}$, $Y_{2}, \ldots Y_{n}$ design on argorithm which can quickly authenticate a randomly chosen $Y_{i}$ but which has modest memory requirements, i.e., does not have a table of $Y_{1}, Y_{2}, \ldots Y_{n}$.

We authenticate the $Y_{i}$ by "divide and conquer". As illustrated in figure 1, define the function $H(1, j, \underline{Y})$ by
1.) $H(1,1 ; \underline{Y})=F\left(Y_{1}\right)$
2.) $H(1, j, \underline{Y})=F(H(1, k, \underline{Y}), H(k+1, j, \underline{Y}))$

Where $k=(1+j) / 2$
for the $\langle i, j\rangle$ pairs of figure 1 and its extensions to larger trees described below.
$H(X, j, Y)$ is a function of $Y_{1}, Y_{i+1}, \ldots Y_{j}$ and can be used to authenticate all of them. $H(1, n, \underline{Y})$ can be used to authenticate $Y_{1}$ through $Y_{n}$ and is only 100 bits, so it can be conveniently stored. We restrict $n$ to powers of 2 to simplify the explanation.

This method lets us selectively authenticate any Mleaf,n $Y_{1}$. that we wish. To see this, we use an example where $n=8$. To authenticate $Y_{5}$, we proceed in the manner illustrated in figure 2:
1.) $H(1,8, \underline{y})$ is already known and authenticated.
2.) $H(1,8, \underline{Y})=F(H(1,4, \underline{Y}), H(5,8, \underline{Y}))$. Send $H(1,4, \underline{Y})$ and $H(5,8, \underline{Y})$ and let the receiver compute $H(1,8, \underline{Y})=$ $F(H(1,4, \underline{Y}), H(5,8, \underline{Y})$. to confirm that they are correct.
3.) The receiver has authenticated $H(5,8, \underline{Y})$. Send $H(5,6, \underline{Y})$ and $H(7,8, \underline{Y})$ and let the receiver compute

$H(5,8, \underline{Y})=F(H(5,6, \underline{Y}), H(7,8, \underline{Y}))$ to confirm that they are correct.
4.) The receiver has authenticated $H(5,6, \underline{Y})$. Send. $H(5,5, \underline{Y})$ and $H(6,6, \underline{Y})$ and let the receiver compute $H(5,6, \underline{y})=F(H(5,5, \underline{Y}), H(6,6, \underline{Y}))$ to confirm that they are correct.
5.) The receiver has authenticated $H(5,5, \underline{Y})$. Send $Y_{5}$ and let the receiver compute $H(5,5, \underline{Y})=F\left(\cdot Y_{5}\right)$ to confirm that it is correct.
6.) The receiver has authenticated $Y_{5}$.

#### Abstract

$i$ Using this method, only $\log _{2} n$ transmissions are required, each of about 200 bits. Close examination of the algorithm will reveal that half the transmissions are redundant.' For example, $H(5,6, \underline{Y})$ can be computed from $H(5,5, \underline{Y})$ and $H(6,6, \underline{Y})$, so there is really no need to send $H(5,6, \underline{y})$. Similarly, $H(5,8, \underline{y})$ can be computed from $H(5,6, \underline{Y})$ and $H(7,8, \underline{Y})$, so $H(5,8, \underline{Y})$ need never be transmitted, either. (The receiver must compute these quantities anyway for proper authentication.) Therefore, to authenticate $Y_{5}$ required only that we have previously authenticated $H(1,8, \underline{Y})$, and that we transmit $Y_{5}, H(6,6, \underline{Y}), H(7,8, \underline{Y})$, and $H(1,4, \underline{Y})$. That is, we require $100 \log _{2} n$ bits of information to authenticate an arbitrary $Y_{i}$.

The method is called tree authentication because the computation of $H(1, \pi, \underline{Y})$ forms a binary tree of recursive calls.

Authenticating a particular leaf $Y_{1}$ in the tree requires only. those values of H() starting from the leaf and progressing to the root, $1 . e ., \operatorname{from} H(1,1, \underline{Y})$ to $H(1, n, \underline{Y})$. $H(1, n, \underline{Y})$ will be. referred to $a s$ the root of the authentication tree, or $R$. The information near the path from $B$ to $H(i, i, \underline{Y})$ required to authenticate $Y_{1}$ will be called the authentication path for $Y_{i}$.

A "proof" that the authentication path actually authenticates the chosen leaf is similar to the "proof" that F defined in chapter II correctiy authenticates its input. Again, more rigorous proofs must await advances in complexity theory.

Although $H()$ produces a 100 bit output, unless additional precautions (outlined in chapter II) are taken, bnly $2^{60}$ or $2^{70}$ operations would suffice to break the system. To force the cryptanalysis to use $2^{100}$ operations it is necessary to make each application of $F$ unique, i.e.. to ușe a family of óne way functions $F_{1}, F_{2}, \ldots$ each one of which is used only once.

The use of tree authentication is now fairly clear. A transmits $Y_{i}$ to $B$. A then transmits the authentication path for $Y_{1}$. $B$ knows $R$, the root of the authentication tree, by prior arrangement. B.can then authenticate $Y_{i}$, and can accept the ith signed message from A as genuine.

The prior arrangements include the computation of $R$ by $A$. If $A$ wishes to be able to sign $1,000,000$ messages, this precomputation will require about an hour, assuming a single encryption takes 10 microseconds. (Fairchild is now (1979) producing a 4-chip set which costs about $\$ i 0$ and which encrypts
faster than this.) The time required for the pre-computation is Inear in $n$, so if $A$ desires to be able to sign $1,000,000,000$ messages, his pre-computation will be about 1000 hours.

The major distinction between this method and digital signatures generated using public key cryptosystems is the requirement that $R$ be changed periodically because only $n$ messages can be signed. With a public key cryptosystem, it is possible to sign an almost indefinite number of messages, and for a user to retain $D_{A}$ for his lifetime if he so desires. In practice, this restriction does not appear to be significant.

If the jth user has a distinct authentication tree with root $R_{j}$, then tree authentication can be used to authenticate $R_{j}$ just as easily as it can be used to authenticate $Y_{i}$. It is not necessary for each user to remember all the $R_{j}$ in order to authenticate then. A central clearinghouse could accept the $R_{j}$ from all $u$ users, and compute $H(1, u, \underline{R})$. This single 100 bit quantity could then be distributed and would serve to authenticate all the $R_{j}$, which would in turn be used to authenticaffe the $Y_{i}$. In practice, $A$ would remember $R_{A}$ and- the authentication path for $R_{A}$ and send them to $P$ along with $Y_{1}$ and the authentication path for $Y_{1}$. (A different method of authentication would be for the clearinghouse to digitally sign "letters of reference" for new users of the system using a one time signature. Kohnfelder [14] has suggested this method for use with public key cryptosystems; see chapter 9.)

Tree authentication and authentication using one time sig-

## A CERTIFIED DIGITAL SIGNATURE

natures can be intermixed to produce systems with all the flexibllity of public key based systems.
i
*

## 1

A must know the authentication path for $Y_{i}$ before transmitting it to $B$. Unfortunately this requires the conputation of $H(1, j, \underline{Y})$ for many different values of 1 and $j$. In the example, it was necessary to compute $H(6,6, \underline{Y}), H(7,8, \underline{Y})$, and $H(1,4, \underline{Y})$ and send them to $B$ along with $Y_{5}$. This is simple for the small tree used in our example, but computing H(4194304,8388608, Y) just prior to sending it would be an intolerable burden. One obvious solution would be to precompute $\mathrm{H}(1, \mathrm{n}, \underline{\mathrm{Y}})$ and to save all the intermediate computations: i.e., precompute all authentication paths. This would certainly allow the quick regeneration of the authentication path for $Y_{i}$, but would require a large memory.

A more satisfactory solution is to note that we wish to authenticate $Y_{1}, Y_{2}, Y_{3}, Y_{4}, \ldots$ in that order. Most of the computations used in reconstructing the authentication path for, $Y_{i}$ can be used in computing the athentication path for $Y_{1+1}$. Only the incremental computations need be performed, and these are quite modest. $\quad$.

In addition, although the $Y_{i}$ must appear to be random, they can actually be generated (safely) in a pseudo-random fashion from a small truly random seed. It is not necessary to keep the $y_{i}$ in memory, but only the small truly random seed used to generate them.
. The result of these observations is an algorithm which can recompute each $Y_{1}$ and its authentication path quickly and with modest memory requirements. Before describing it we review the problem:

Problem Definition: Sequentially generate the authentication paths for $Y_{1}, Y_{2}, Y_{3}, \ldots Y_{n}$ with modest time and space bounds.

The simplest way to understand how an algorithm can efficiently generate all authentication paths is to generate all the authentication paths for a small example.

An example of all authentication paths for $n=8$ is:
$:$

> leaf
authentication path
$H(1,8, \underline{Y}) H(5,8, \underline{Y}) H(3,4, \underline{Y}) H(2,2, \underline{Y})$
$Y_{2}$
$H(1,8, \underline{Y}) H(5,8, \underline{Y}) H(3,4, \underline{Y}) H(1,1, \underline{Y})$
$Y_{3} \quad H(1,8, \underline{Y}) H(5,8, \underline{Y}) H(1,2, \underline{Y}) H(4,4, \underline{Y})$
$Y_{4}$
$H(7,8, \underline{Y}) H(5,8, \underline{Y}) H(1,2, \underline{Y}) H(3,3, \underline{Y})$
$Y_{5}$
$-H\left(\frac{1}{1}, 8, \underline{Y}\right) H(1,4, \underline{Y}) H(7,8, \underline{Y}) H(6,6, \underline{Y})$
$Y_{6}$
$H(1,8, \underline{Y}) H(1,4, \underline{Y}) H(7,8, \underline{Y}) H(5,5, \underline{Y})$
$Y_{7}$
$H(1,8, \underline{Y}) H(1,4, \underline{Y}) H(5,6, \underline{Y}) H(8,8, \underline{Y})$
$Y_{8}$
$H(1,8, \underline{Y}) H(1,4, \underline{Y}) H(5,6, \underline{Y}) H(7,7, \underline{Y})$

TABLE 1

If we had to separately compute each entry in table 1 , then it would be impossible to efficiently generate the authentication paths. Fortunately, there is a great deal of duplication. If we eliminate all duplicate entries, then table 1 becomes table 2:

TABLE :

Clearly we can generate all authentication paths by separately computing each of the $2 \mathrm{n}-1$ entries in table 2, but this would require too much memory, and it is not clear what the execution time would be. We first consider the execution time, the memory requirement will be considered later. Recause all computations must eventually be defined in terms of the
underlying encryption function $C(k e y, p l a i n t e x t)$, it seems ap-. propriate to define execution time requirements in terms of the number of applications of $C$. One application of $C$ counts as. one "unit" of computation. We shall call this "unit" the "et," (pronounced eetee) which stands for "encryption time."

Computing $F$ requires a number of ets proportional to the length of its input. In particular, if the input is composed of 100 k bits, then $F$ requires $k-1$ ets (see chapter. 2 ).

First, we must determine the cost of computing the individual entries. The algorithm for computing $H(i, j, \underline{Y})$ from $\underline{Y}$ does a tree traversal of the subtree whose leaves are $Y_{i}, Y_{i+1}$, $Y_{i+2}, \ldots Y_{j}$. At each non-leaf node in this triversal it does 1 et of computation (one application of $F$ to a 200-bit argument). A tree with $j-i+1$ leaves has $j-1$ non-leaf nodes, i.e., $j-i$ nodes internal to the tree. For example, as tree with 8 leaves has $4+3+2+1=10$ internal nodes. Because there are j-1 non-leaf nodes, computing $H(i, j, \underline{Y})$ requires $j-i$ ets, excluding the leaves. The computations required to regeneraté a leaf (using a truly random seed in a pseudo random number generator) will be fixed and finite. Let $r$ be the (fixed) number of ets required to regenerate a leaf. There are ( $j-i+1$ ) leaves, so the overall cost of computing $H(i, j, \underline{Y})$ is $(j-i)+$ ( $j-i+1$ ) $\cdot r$ ets. In practice $r$ will be a few hundred, so we can approximate this by (j-i+1) • $r$ ets.

We can now approximate the cost of computing each entry in table 2. There are $n$ entries which require about $r$ ets, $n / 2$
entries which require about $2 r$ ets, $n / 4$ entries which require. about $4 r$ ets, and $n / 8$ entries which require about 8 r ets. This means that the total cost of computing all entries in a. single column is about 8 rets. There are 4 columns, so the total computational effort is about $4.8 \mathrm{r}=32 \mathrm{r}$ ets. In general, the computational effort required to compute table 2 will be $n \cdot\left(1+\log _{2} n\right) \cdot r$ ets. This is because computing all the entries in each column will require $n \cdot r$ ets, and there are 1 $+\log _{2} n$ columns.

This result implies that an algorithm which sequentially generated the authentication paths would require an average of about

$$
\begin{equation*}
r \cdot \log _{2} n \tag{5.1}
\end{equation*}
$$

ets per path, where $r$ is a constant representing the number of ets required to regenerate a leaf. This is quiterreasonable.

Although the time required to generate each authentication
path is small, we must also insure that the space required is small and that the computational burden is smoothly distributed as a function of time. We can do this by again looking at table 2. As we sequentially generate the authentication paths, we will sequentially gip through the entries in a column. This implies that at any point in time there are only two entries in a colimn of any interest to us: the entry needed in the current authentication path, and the entry immediately following it. We must know the entry in the current authentication path, for without it, we could not generate that path. At some point, we
will need the next entry in the column to generate the next authentication path. Because it might require a great deal of effort to compute the next entry (e.g. to compute $H(1,4, \underline{y})$ ), we . need to compute it incrementally, and to begin computing it well in advance of the tine we will actually require it to generate an authentication path.

As an example, $\mathrm{H}(5,8, \underline{\mathrm{Y}})$ is required in the authentication paths for $Y_{1}, Y_{2}, Y_{3}$, and $Y_{4}$ while $H(1,4, \underline{Y})$ is required in the paths for $Y_{5}, Y_{6}, Y_{7}$, and $Y_{8}$. The values of $H()$ for the first authentication path must be precomputed with some delay (discussed below). Once this precomputation is corplete, the succeeding values of $H()$ required in succeeding authentication paths must be incrementally computed. As we generate the first 4 authentication paths, we must be continuously computing $H(1,4, \underline{Y})$ even though it is not needed until we reach $Y_{5}$. If we waited until time 5 to start computing it, it would take about $4 r$ ets to compute and entail some delay. Ey computing it during times 1 through 4, a processor capable of only rets/unít time is needed. In general, if the tree is of depth $k$ it will take $2^{k-1}$. $r$ ets to compute the second element in the second column, but there are $?^{k-1}$ tive units in which to compute it, again requiring a processor capable of only $r$ ets/unit time.

Similarly, we must start computing the second element in the third column, $H(1,2, \underline{y})$, when we generate the first authentication path. It takes about $2 r$ ets to compute this element ( $2^{k-2}$ in general), but there are 2 time units ( $2^{k-2}$ in gen-
eral), in which to do this, so the processor for computing en-. tries in the third column also needs to operate at only $r$ ets/mit time. It. is seen that it takes $2^{k-i-1}$. $r$ ets to com-. pute the next entry in the ith column and that there are $2^{k-i-1}$ time units in which to do this. Thus, only one processor is needed per column $\left(\log _{2} n\right.$ in $a l l$, and each processor need operate at only r ets/unit time.

If we assume a convenient block size (of 100 bits) and if we ignore constant factors, then the menory required by this method can be computed. We can first determine the memory required by the computations in each column, and then sum over all $\log _{2} n$ columns. We must have one block to store the current entry in the column. We must also have enough memory to compute the next entry in the colum. The memory required while computing $H(i, j, \underline{Y})$ is $\underset{\sim}{1}+\log _{2}(j-i+1)$ blocks. This assumes a straightforward recursive algorithm whose maximum stack depth will be $1+\log _{2}(j-i+1)$. The memory required to recompute a leaf (to reconpute $H(i, 1, \underline{Y})$ ) is ignored because it its small (a few blocks), constant, and the same memory can be shared by all the columns. Representing the memory requirements of $H()$ in a new table in the same format as table 2 gives table 3:

A CERTIFIED DIGITAL SIGNATURE

| leaf | memory required to compute entries |  |  |
| :---: | :---: | :---: | :---: |
| in authentication path (in blocks) |  |  |  |
| $Y_{1}$ | 4 | 3 | 2 |

Table 3 shows the memory required to compute each'entry in table 2. Clearly the memory required to compute $H(i, i, \underline{Y})$ is 1 . The memory required to compute $H(1,2, \underline{Y})=1$ + the memory required to compute $H(1,1, \underline{Y})$ since we first compute $H(1,1, \underline{Y})$ and, must remember it to compute $H(1,2, \underline{Y})$. Similarly, to complite $H\left(1,2^{t}, \underline{Y}\right)$ requires one more memory location than was needed for $H\left(1,2^{t-1}, \underline{Y}\right)$. The memory required for each column will be about the memory required during the computation of a single entry in the column because once an entry is computed, the memory is avallable to compute the next entry and the old entry is discarded after use. This means the total memory required will be about: $3+2+1=6$ blocks. (This assumes we do not recompute $H(1,8, \underline{y}))$.

For $n$ in general, there are $\log _{2} n$ columns and each column requires, on an average, $\left(\log _{2} n\right) / 2$ blocks so the total memory required will be on the order of:
$\left(\log _{2} n\right)^{2} / 2$ blocks

This means that the memory required when $n=2^{20}$ (1,048,576) is about $20 \cdot 20 / 2=200$ blocks. For 100 bit blocks, this means 20 kilobits, or 2.5 kilobytes. Other overhead might amount to 2 or 3 kilobytes, giving an algorithm which requires 5 or 6 kilobytes of memory, in total:

Readers interested in implementing this tedhnique can use the following program, written in a Pascal-like language with two multiprocessing primitives added:
1.) While <condition> wait $*$
2.) Fork <statement>

In addition, the function "MakeY(i)" will regenerate the value of $y_{i}$ from the truly randon seed.

Declare flag: array[0.: $\left.\log _{2}(n)-1\right]$ of integer;
AP: array[0. $\left.{ }^{[ } \log _{2}(n)-1\right]$ of block;

$\checkmark$
The general structure of this program is simple: the main routine forks off $\log _{2} n$ processes to deal with the $\log _{2} n$ columns. Then it prints each authentication path by sequentially printing an output from each process. The major omission in this program is the rate at which each process does its
computations. It should be clear from the previous discussion that each process has adequate time to compute its next output.

There are three major ways of improving this algorithm. First, each process is completely independent of the other processes. However, separate processes often require the same intermediate values of H() , and could compute these values once and share the result.

Second, values of $H()$ are discarded after use, and must be recomputed later when needed. While saving all values of H() takes too much memory, saving some values can reduce the computation time and also reduce memory requirements. The reduction in memory is because of the savings in memory when the saved value is not recomputed. Recomputing a value requires memory for the computation, while saving the value requires only a single block.

Finally, the memory requirements can be reduced by carefully scheduling the processes. While it is true that each process requires about $\log _{2} n$ blocks of memory, this is a max ${ }_{f}$ imum requirement, not a typical requirement., By speeding up the execution of a process when it is using a lot of memory, and then slowing it down when it is using little memory, the average memory requirement of a process (measured in blockseconds) can be greatly reduced. By scheduling the processes so that the peak memory requirements of one process coincide with the minimum memory requirements of other processes, the
total menory required can be reduced.
All three approaches deserve more careful study because the potential savings in time and space might be large. Even. without such improvements the technique is completely practical.

Before the time requirements of the algorithm can be fully analyzed, a description of MakeY is needed: 1.e., we must determine $r$ in equation (5.1). If we assume that the improved version of the Lamport-Diffie algorithos is used, then MakeY must generate pseudo-random $X_{i}$ vectors, from which $Y_{i}$ vectors can then be generated. If the one way hashed messages are all 100 bits long, then the $X_{i}$ vectors will have $100+\log _{2} 100=$ 107 elements.

The $X_{i}$ vectors can be generated using a conventional cipher, $C(k e y, p l a i n t e x t)$. A single 200 bit secret key ${ }^{\text {is }}$ required as the "seed" of the pseudo-random process which generates the $X_{i}$ vectors. The output of $C$ is always 100 bits, and the input must be 100 bits or fewer, (if fewer, $0^{\prime}$ s are append-' ed). We can now define $x_{i, j}$ as

$$
x_{1, j}=c(\text { seedkey, }\langle i, j\rangle)
$$

where "seedkey" is the 200 bit secret and truly random key used as the "seed" of this somewhat unconventional pseudo-random number generator. The subscript $i$ is in the range 1 to $n$, while the subscript $j$ is in the range 1 to 107. There are $n$ possible messages, each 100 bits in length. Each $X_{i}$ is a.vec-
$\operatorname{tor} x_{1,1}, x_{1,2}, \ldots x_{1,107^{\circ}}$
Determining any $x_{1, j}$ knowing some of the other $x_{i, j}$ 's is equivalent to the problem of cryptanalyzing $C$ under a known plaintext attack. If $C$ is a good encryption function, it will not be possible to determine any of the $x_{i, j}$ without already knowing the key. The secret vectors $X_{i}$ are therefore safe.

We know that $y_{i, j}=F\left(x_{i, j}\right)$, and that $H(i, 1, \underline{Y})=F\left(Y_{i}\right)=$ $F\left(y_{i, 1}, y_{1,2}, y_{1,3}, \ldots y_{1,107}\right)$. The cost of computing $F\left(Y_{i}\right)$ is 106 ets, because $Y_{i}$ is $107 \cdot 100$ bits long. The total effort to compute $H(i, i, \underline{Y})$ is the effort to generate the elements of the $X_{i}$ vector, plus the effort to compute $F\left(x_{1,1}\right), F\left(x_{i}, 2\right), \ldots$ $F\left(x_{i, n}\right)$, plus the effort to compute $F\left(Y_{i}\right)$. This is 107 ets to compute the $X_{i}$ vector, 107 ets to compute the $Y_{i}$ vector, and 106 ets to compute $F\left(Y_{i}\right)=H(i, i, \underline{Y})$. This is a total of 320 ets to regenerate each leaf in the authentication tree.

Using equation (5.1), we know that the cost per authentication path is $320 \log _{2} n$ ets. For $n=2^{20}$, this is 6400 ets. To generate authentication paths at the rate of one per second implies 1 et is about 160 microseconds. While easily done in hardware, this speed is difficult to ettain in software on current computers. Reducing the number of ets per authentication path is a worthwhile goal. This can effectively be done by reducing either the cost of computing $H(1,1, \underline{y})$, or by reducing the number of times that $H(i, i, \underline{Y})$ has to be computed.

As mentioned earlier, keeping previously computed values of H() rather than discarding them and sharing commonly, used
values of H() among the $\log _{2} n$ processes reduces the cost of computing each authentication path. In fact, a reduction from over 6000 ets to about 1300 ets (for $n=2^{20}$ ) can be attained. (To put this in perspective, Make requires 320 efts and must be executed at least once per authentication path. Therefore, 320 ats is the absolute minimum that can be attained without modiflying Make.) This means the path regeneration algorithm can. run in reasonable time (a few seconds) even when the underlying encryption function, $C$, is implemented in software.

## A CERTIFIED DIGITAL SIGNATURE

## 6. Conclusion

Digital signature systems not requiring public key cryptosystems are possible and desirable because they are easy to certify. Such a system was described which had modest space and time requirements and-a signature size of about 15 kilo bits: The method described can be implemented at once, with no delay due to certification.

## VI. THE TRAPDOOR KNAPSACK

## 1. Introduction

This chapter describes a public key cryptosystem based on the knapsack problem. Given a one-dimensional kmapsack of length $S$ and $n$ rods of lengths $a_{1}, a_{2}, \ldots, a_{n}$, the ${ }^{n}$ knapsack problem" is to find a subset of the rods which exactly fills the knapsack, if such a subset exists. Equivalently, find a binary $n$-vector $\underline{x}$ such that $S=\underline{a} \mathbb{x}$, if such an $\underline{x}$ exists, (* applied to vectors denotes dot product.)

A supposed solution $\underline{x}$ is easily checked in at most $n$ additions, but finding a solution is believed to require a number of operations which grows exponentially in $n$. Exhaustive, trial and error search over all $2^{n}$ possible $\underline{x}^{\prime}$ s is computationally infeasible if $n$ is larger than one or two hundred. The best published method for solving knapsacks of the form considered here requires $2^{\text {n/2 }}$ complexity both in time and memory [10]. In addition, Schroeppel [33] has devised an algorithm which takes $O\left(2^{n / 2}\right)$ time and $O\left(2^{n / 4}\right)$ space. Theory supports the belief that the knapsack problem is hard because it is an NP-complete problem [footnote page 81], and is therefore one of the most difficult computational problems of a cryptographic nature [1 pp 363-404] [6]. Its degree of difficulty, however, is crucially dependent on the choice of $a$. If $a=\left(1,2,4, \ldots 2^{n-1}\right)$, then solving for $\underline{x}$ is equivalent to finding the binary
representation of S. Somewhat less trivially, if for all i,

$$
a_{i}>\sum_{j=1}^{i-1} a_{j}
$$

then $\underline{x}$ is also easily found: $x_{n}=1$ if and only if $S \geq a_{n}$ and, for $i=n-1, n-2, \ldots 1, x_{i}=1$ if and only if
n

$$
\begin{equation*}
s-\sum_{j=i+1} x_{j} \cdot a_{j} \geq a_{i} \tag{6.2}
\end{equation*}
$$

While the theory of NP-complete problems and these examples demonstrate that the knapsack problem is only difficult from a worst case point of view, it is probably true that choosing the $a_{i}$ independently and uniformly from the integers between 1 and $2^{\text {n }}$ generates a difficult problem with probability tending to one as $n$ tends to infinity. While several efficient algorithos exist for solving the knapsack problem under special conditions [10], [11], [16], none of these special conditions is applicable to trap door knapsacks generated as suggested in this chapter.

A trap door knapsack [6] is one in which careful choice of a allows the designer to easily solve for any $\underline{x}$, but which prevents anyone else from finding the solution. We will describe one method for constructing a trap door knapsack, and another (multiplicative) method due to Hellman is described in [21]. We first indicate how knapsacks can be used to hide information. Each user I in a system generates a trap door knap-
sack vector, $\underline{a}(I)$, and places it in a public file with his name and address. When someone wishes to send the binary information vector $x$ to the $I t h$ user, he sends $S=\underline{x} \underset{a}{ }(I)$. The in-. tended recipient can recover $\underline{x}$ from $S$ but no one else can. Section 5 shows how trap door knapsacks can be used to generate electronic,signatures and receipts [6].

Before proceeding, a word of caution is in order. First, as is always the case in computational cryptography, we cannot yet prove that the systems described in this chapter are secure. For brevity, however, we will not continue to repeat this. Second, the trap door knapsacks described in this chapter form a proper subset of all possible knapsacks and their solutions are therefore not necessarily as difficult as for the hardest knapsacks, ano it is the hardest knapsacks with which NP theory is concerned.

## 2. A Method for Constructing Trap Door Knapsacks

The designer chooses two large numbers, $m$ and $w$, such that $w$ is invertible modulo $m$ (equivalently $\operatorname{GCD}(w, m)=1$ ). He selects a knapsack vector, $a^{\prime}$ which satisfies (6.1) and therefore allows easy solution of $S^{\prime}=a^{\prime}$ " $\underline{x}$. He then transforms the easily solved knapsack vector a' into a trap door knapsack vector a via the relation

$$
\begin{equation*}
a_{i}=w \cdot a_{i}^{\prime} \bmod m \tag{6.3}
\end{equation*}
$$

The $a_{i}$ are pseudo-randomly distributed and it therefore appears that anyone who knows $a$, but not $w$ and $m$, would have great difficulty in solving a knapsack problem involving a. The designer, on the other hand, can easily compute

$$
\begin{align*}
s^{\prime} & =w^{-1} \cdot S \bmod m  \tag{6.4}\\
& =w^{-1} \cdot \sum x_{i} \cdot a_{i} \bmod m  \tag{6.5}\\
& =w^{-1} \cdot \sum x_{i} \cdot w \cdot a_{i}^{\prime} \bmod m  \tag{6,6}\\
& =\sum x_{i} \cdot a_{i}^{\prime} \bmod m \tag{6.7}
\end{align*}
$$

If $m$ is chosen so that

$$
\begin{equation*}
m>\sum a_{i} \tag{6.8}
\end{equation*}
$$

then (6.7) implies that $S^{\prime}$ is equal to $\sum x_{i} \cdot a^{\prime}{ }_{i}$ in integer arithmetic as well as mod $\mathbb{0}$. This knapsack is easily solved for $\underline{x}$, which is also the solution to the apparently difficult, but trap door, knapsack problem $s=\underline{a}$ * $\underline{x}$.

To help make these ideas clearer, we give a small example with $n=5$. Taking $m=8443, a^{\prime}=(171,196,457,1191,2410)$, and $w=2550$ (so $w^{-1}=3950$ ), then $\underline{a}=(5457,1663,216,6013,7439)$.

Given $S=1663+6013+7439=15115$, the designer computes

$$
\begin{align*}
S^{\prime} & =w^{-1} \cdot s \quad \bmod m \\
& =3950 \cdot 15115 \bmod 8443 \\
& =3797
\end{align*}
$$

Recause $S^{\prime}>a^{\prime}{ }_{5}$, he determines that $x_{5}=1$. Then, using (6.2) for the $\underline{a}^{\prime}$. vector, he determines that $x_{4}=1, x_{3}=0, x_{2}=1$, $x_{1}=0$, which is also the correct solution to $S=\underline{a}^{*} \underline{x}$.

Anyone else who does not know $m$, $a^{\prime}$, and w has great difficulty in solving for $\underline{x}$ in $S=\underline{a}$ * $\underline{x}$ even though the general method used for generating the trap door knapsack vector a must be public. His task can be further complicated by scrambling the order of the $a_{i}$, and by adding different random multiples of $m$ to each of the $a_{i}$.

The example given was extremely small in size and only intended to illustrate the technique. Using $n=100$, which is the bottom end of the usable range for secure systems, $m$ can be chosen uniformly from the numbers between $2^{201}+1$ and $2^{202}-$ 1: a', can be chosen uniformly from the range $\left[1,2^{100}\right] ; a_{2}^{\prime}$ can be chosen uniformly from $\left[2^{100}+1,2 \cdot 2^{100}\right] ; a_{3}^{\prime}$ can be chosen uniformly from $\left[3 \cdot 2^{100}+1,4 \cdot 2^{100}\right] ; \quad . . \quad a_{i}$ can be chosen uniformly from $\left.\left[\left(2^{i-1}-1\right) \cdot 2^{100}+1,2^{i-1} \cdot 2^{100}\right)\right] ; \ldots a_{100}$ can be chosen uniformly from $\left[\left(2^{99}-1\right) \cdot 2^{100}+1,2^{99} \cdot 2^{100}\right]$; and $w$ can be chosen uniformly from [2, m-2] and then repeatedly divided by the greatest common divisor of $w$ and $m$, to yield the value of $w$ that is actually used.

These choices ensure that (6.8) is met and that an op-

## THE TRAPDOOR KNAPSACK

ponent has at least $2^{100}$ possibilities for each parameter and hence cannot search over even one of them. Note that each $a_{i}$ will be pseudo-randomly distributed between 1 and $\mathrm{m}-1$ and hence will require a 202 bit representation. $S$ will require a 209 bit representation, so there is a 2.09:1 data expansion from $\underline{x}$ to S .

## 3. An Iterative Method

This section discusses techniques for improving the security and utility of the basic methods.

In the first method we transformed a hard and apparently very difficult knapsack problem, $\underline{a}$, into a very simple and easily solved knapsack problem, ${ }^{\prime}$, by means of the transformation:

$$
\begin{equation*}
a_{i}{ }_{\underline{i}}=w^{-1} \cdot a_{i} \bmod m \tag{6.15}
\end{equation*}
$$

We could solve a knapsack involving a because we could solve a knapsack involving a'. Notice, though, that it does not matter why we are able to solve knapsacks involving a', all that matters is that we can solve them. Rather than requiring that a' satisfy (6.1), we could require that $a^{\prime}$ be transformable into a nek problem, a'', by the transformation:

$$
\begin{equation*}
a^{\prime \prime}{ }_{i}=w^{\prime-1} \cdot a_{i}^{\prime} \bmod m^{\prime} \tag{6.16}
\end{equation*}
$$

where the new problem, a' ', satisfies (6.1), or is otherwise easy to solve. Having done the transformation twice, there is no problem in doing it a third time. That is, we select an a' which is easy to solve, not because it satisfies (6.1), but because it can be transformed into a'"', which is easy to solve, by:

$$
\begin{equation*}
\underline{a}^{\prime \prime \prime}{ }_{i}=w^{\prime \prime} \cdot \underline{a}^{\prime \prime}{ }_{i} \bmod m^{\prime \prime} \tag{6.17}
\end{equation*}
$$

It is clear that we can repeat this process as often as we wish.

With each successive transformation, the structure in the
publicly known vector, a, becomes more and more obscure. In essence, we are encrypting the simple knapsack vector by the repeated application of a transformation which preserves the basic structure of the problem. The final result a appears to be a collection of randon numbers. The fact that the problem can be easily solved has been totally obscured.

The effect of repeating the process several times is very different from that obtained with certain ciphers, such as a simple substitution. A simple substitution cipher is not strengthened by repetition because the composition of two substitution ciphers is yet another substitution cipher. The ( $w, m$ ) transformations do not have this closure property. The following example shows that the repetition of two ( $w, m$ ) transforms is not in general equivalent to a single ( $w, m$ ) transform.

$$
\text { If } w=3, m=89, w^{\prime}=17, m^{\prime}=47, \text { and } \underline{a}^{\prime \prime}=(5,10,20)
$$

then $\underline{a}^{\prime}=(38,29,11)$ and $\underline{a}=(25,87,33)$. Assume there exists $\hat{w}$ and m such that

$$
\begin{equation*}
\underline{a}=\hat{w} \cdot \underline{a}^{i} \cdot \bmod \hat{m} \tag{6.18}
\end{equation*}
$$

Then $a_{1}=25$ and $a^{\prime \prime}{ }_{1}=5$ implies that

$$
\begin{equation*}
25=\hat{\mathbf{w}} \cdot 5 \bmod \hat{m} \tag{6.19}
\end{equation*}
$$

From this we have

$$
\begin{equation*}
2 \cdot 25=\hat{\mathrm{w}} \cdot 2 \cdot 5 \text { mod } \hat{\mathrm{in}} \tag{6.20}
\end{equation*}
$$

or

$$
\begin{equation*}
50=\hat{\mathrm{W}} \cdot 10 \bmod \hat{\mathrm{~m}} \tag{6.21}
\end{equation*}
$$

But now the relation $a_{2}=87$ and $a^{11}{ }_{2}=10$ implies that

$$
\begin{equation*}
87=\hat{W} \cdot 10 \bmod \hat{\mathrm{~m}} \tag{6.22}
\end{equation*}
$$

so $87=50 \bmod \hat{m}$, or $37=0 \bmod \hat{m}$, which implies that $\hat{m}=37$. Equation (6.19) then becomes

$$
\begin{equation*}
25=\hat{m} \cdot 5 \bmod 37 \tag{6.23}
\end{equation*}
$$

so $\hat{w}=5$. But if $\hat{w}=5$, and $\hat{m}=37$, then equation (6.18) for $a_{3}=33$ and $a^{\prime \prime}{ }_{3}=20$ becomes

$$
\begin{equation*}
33=5 \cdot 20 \bmod 37 \tag{6.24}
\end{equation*}
$$

or $33=26$ mod 37 , a contradiction. We conclude that no such $\hat{\mathbf{w}}$ and $\mathfrak{I l}$ can exist.

The original, easy to solve knapsack vector can meet any condition, such as (6.1) which guarantees that it is easy to solve.

It is important to consider the rate of growth of $\underline{a}$, because this rate determines the data expansion involved in transmitting the $n$ bit vector $\underline{x}$ as the larger quantity $S$. The rate of growth depends on the method of selecting the numbers but, with $n=100$, each $a_{i}$ need be at most 7 bits larger than the corresponding $a_{i}$, each $a^{\prime}{ }_{i}$ need be at most 7 bits larger than a'' ${ }_{i}$, etc. etc. Each successive stage of the transformation need increase the size of the problem by only a small, fixed amount. Repeating the transformation 20 times will add at most 140 bits to each $a_{i}$. If each $a_{i}$ is 200 bits long to begin with, then they need only be 340 bits long after 20 stages, and $S$ is representable in 347 bits. The data expansion is then only 3.47:1.

## 4. Compressing The-Public File

As described above, the Ith user must place his trap door. knapsack vector, $\underline{a}(I)$, in a public file. The Jth user can then look up $a(I)$, and send a message $x$ to $I$, hidden as $S=a(I) *$ x. To avoid storing the rather large vector $a(I), J$ could ask I to transmit $a(I)$ to him. But, unless $J$ has some method for testing $\underset{(I)}{ }(I)$ user $K$ might fool $J$ by sending him $\underset{( }{ }(K)$, and saying it was $a(I)$. $J$ would then mistakenly tell all his secrets to $K$. A method is needed for $J$ to convince himself that he was really sent $\underline{a}(I)$. With a public file, each user can make one personal appearance when depositing his vector and, after so identifying himself to the system, he could identify (authenticate) himself to any user by his ability to decipher messages hidden with his vector. The file itself must be protected, but this is relatively easy because only write protection is needed.

To preserve this authentication benefit of the public file, but to reduce its size(20 or more kilobits per user) we suggest storing a 100 bit onewway hash total, $h[\underline{a}(I)]$, instead of $a(I)$ itself. When $J$ receives $a(I)$ from $I$ he computes $h[a(I)]$ and checks this against $I$ 's value stored in the public file. The hash function, $h$, must be a one-way function [6], [38], [7], [28] so that $K$ cannot generate a new vector $a(K)$ such thet $h[\underline{a}(K)]=h[(\underline{a}(I)]$, without having to perform a contputationally impossible feat.

Allowing 200 bits for storing the user's name and address, (or "phone number"), the public file now contains 300 bits, instead of over 20 kilobits, per user. A system with a million. users requires a 300 million bit, instead of a 20 billion bit, public file. Transmission costs are comparable for both implementations.

A 100 bit number can be coded as 20 alphanumeric characters, which is small enough to fit in a phone book. A typical entry would look like this:

Joe Smith..... . 497-1573
KSDJR E6K65 3GFVM OMK4K
The extra entry, KSDJR E6K65 3GFVM OMK4K, is the one-way hash total of Smith's trap door knapsack vector, a(Smith). With this information, we can call up Smith, and hold a secure conversation with him, which no one else can understand. We do not need to have met smith previously to know we are talking with him or for him to know he is talking with us.

Transmitting 20 kilobits on a high speed, 50 kbps link, takes 0.4 second, but on a low speed, 300 bps link, it takes over a minute. The transmission time can be reduced by a factor of 5 , to about 4 kilobits, which takes less than 15 seconds to transmit at 300 bps , by cutting the number of $a_{i}$ to $n=20$. The vector $\underline{x}$, however, now has only 20 binary elements, which is small enough to allow solution by exhaustive search. To malntain security, the information in the $\underline{x}$ vector must be increased to about 100 bits, while keeping $n=20$. This can be
done by allowing each element, $x_{i}$, to take on values in the set $\{0,1,2,3, \ldots, 31\}$, instead of just in $\{0,1\}$. Specifying each $x_{1}$ takes 5 bits, and specifying the whole vector $\underline{x}$ takes 100 bits. Equation (6.1) must now be modified to

$$
a_{i}>31 \cdot \sum_{j=1}^{i-1} a_{j}
$$

If $n$ is reduced to 1 and the single element of the $\underline{x}$ vector assumes a value in $\left\{0,1,2, \ldots 2^{100}-1\right\}$, then the system is easily broken because

$$
\begin{equation*}
x=S / a \tag{6.26}
\end{equation*}
$$

When $n=2$, the system can also be broken easily, by an algorithm similar in spirit to the greatest common divisor algorithm. It seems that small values of $n$ weaken the system, and further research is needed to determine how small $n$ can be, while still preserving security. The value $n=20$ suggested above must be treated with suspicion until an adequate certificational study is conducted.

## 5. Signatures

As discussed in [6], the need for a digital equivalent of $\cdot$ a written signature is a major barrier to the replacement of physical mall by teleprocessing systems. Usual digital authenticators protect against third party forgeries, but cannot be used to settle disputes between the transmitter and receiver as to what message, if any, was sent. A true digital signature allows the recipient to prove that a particular message was sent to him by a particular person. Obviously, it must be impossible for the recipient to alter the contents of the message and generate the corresponding signature, but it must be easy for him to check the validity of a signature for any message from any user. A digital signature can also be used to generate receipts. The recipient signs a message saying, "I have received the following message: TEXT." This section describes how trap door knapsacks might be used to generate such signatures and receipts.

If every $S$ in some large fixed range had an inverse image $\underline{x}$ then it could be used to provide signatures. When the Ith user wanted to send the message $m$ he would compute and transmit $\underline{x}$ such that $\underline{a}(I) * \underline{x}=m$. The recipient could easily compute m from $x$ and, by checking a date/time field (or some other redundancy in m), determine that the message was authentic. Because the recipient could not generate such an $\underline{x}$ he saves $\underline{x}$ as proof that the Ith user sent him the message $m$.

This method of generating signatures can be modified to work when the density of solutions (the fraction of $S$ between 0 and $\sum \dot{a}_{1}$ which have solutions to $x^{a}=S$ ) is less than 1 , provided it is not too small. The message $m$ is sent in plaintext form, or encrypted if eavesdropping is a threat, and a sequence of oneway functions [6], [38], [7], [28] $y_{1}=F_{1}(m), y_{2}$ $=F_{2}(m), \ldots$ are computed. The transmitter then seeks inverse Images for $y_{1}, y_{2}, \ldots$ until one is found and appends the corresponding $x$ to $m$ as a signature. The receiver computes $y=$ a $\underline{x}$ and checks that $y$ is equal to $y_{k}$ with $k$ not too large, for example at most 10 times the expected value of $k$.

The sequence of functions $F_{1}(\cdot)$ can be as simple as;

$$
\begin{equation*}
F_{i}(m)=F(m)+i \tag{6.20a}
\end{equation*}
$$

or

$$
\begin{equation*}
F_{i}(m)=F(m+i) \tag{6.20b}
\end{equation*}
$$

where $F(\cdot)$ is a one-way function. It is necessary that the range of $F(\cdot)$ have at least $2^{100}$ values to foil trial and error attempts at forgery. If the message is much longer than 100 bits, the expansion caused by the addition of a 100 bit authentication field is unimportant.

If the trap door knapsack vector were generated as suggested at the end of section 2 , the solution density would be less than $1 /\left(2^{100}\right)$, and over $2^{100} y_{k}$ would have to be tried, on the average; before one with a solution was found. It is posm sible, however, to use the iterative method of section 3 to obtain a solution density of approximately $1 /\left(10^{4}\right)$ with two
iterations or $1 /\left(10^{6}\right)$ with three iterations, when $n=100$. First, a knapsack vector $\underline{E}^{\text {' }}$ with a solution density near 1 is selected. If $\underline{a}^{\prime \prime}=\left(1,2,4,8, \ldots, 2^{99}\right)$ then the solution density is 1, but increasing some of the larger a'; need not greatly reduce the solution density. For example, $(1,2,4,8,17,35,68,142)$ has a solution density of .92 and still satisfies (6.1). Such choices may not be necessary, but they provide an additional margin of safety at almost no additional cost.

After selecting $a^{\prime \prime}$, parameters $m^{\prime}$ and $w^{\prime \prime}$ are chosen such that $m$ ' $>\quad a^{\prime \prime}{ }_{i}$ and $w^{-1}$ exists modulo $m^{\prime}$. The weak trap door knapsack vector

$$
\underline{a}^{\prime}=w^{\prime} \cdot \underline{a}^{\prime \prime} \quad \bmod m^{\prime} . \quad(6.27)
$$

is then computed. New parameters $m>\sum \underline{e}^{\prime} 1^{\text {and }} w$ (with $w^{-1}$ existing mod $m$ ) are chosen, and the more secure trap door knapsack vector

$$
\underline{a}=w \cdot \underline{a}^{1} \quad \bmod m \quad(6.28)
$$

is computed. The process can be iterated more than twice to obtain the final vector, a. but the solution density typically decreases by a factor of $n / 2$ with each iteration. When used for hiding information this decrease is of little importence, but when used for signatures, several iterations are all that can be afforded because of the need for a high solution density. With so few iterations, $i t$ is possible for two adjacent $a_{j}$ to be in the same ratio (usually $2: 1$ ) as they were in the $a$ vector. This weakness can be overcome by adding multiples of
$\|^{\prime \prime}$ (or m) to a subset of the $a_{i}$ (or $a_{i}$ ) which suffer from this problem. This decreases the solution density somewhat, and accounts for our $1 /\left(10^{4}\right)$ and $1 /\left(10^{6}\right)$ estimates for two and three. iterations when $n=100$.

A small example is again helpful in illustrating the method. Starting with

$$
\begin{equation*}
a^{\prime \prime}=(1,2,4,8,17,35,68,142) \tag{6.29}
\end{equation*}
$$

whose components sum to 277 , we choose $m^{\prime}=291$ and $w^{\prime}=176$ $\left(w^{-1}=167\right)$, resulting in

$$
\begin{equation*}
\underline{a}^{\prime}=(176,61,122,244,82,49,37,257) \tag{6.30}
\end{equation*}
$$

The second, third and fourth components are in the ratio of $2: 1$ which can be hidden by adding m" to the third component to obtain the new vector

$$
\begin{equation*}
\underline{a}^{\prime}=(176,61,413,244,82,49,37,257) \tag{6.31}
\end{equation*}
$$

whose components sum to 1319. Choosing $m=1343, w=498 \mathrm{w}^{-1}$ $=$ 925) yields

$$
\begin{equation*}
\underline{a}=(353,832,195,642,546,228,967,401) \tag{6.32}
\end{equation*}
$$

whose components sum to 4164 . The density of solutions using a is $256 / 4164=.061$ so approximately 16 attempts are needed, on the average, to obtain a signature. This agrees well with the estimated range of $n^{2} / 4=16$ to $n^{2}=64$.

The density of solutions can be increased by restricting the $y_{k}$ to lie near the middle of the range $\left(0, \sum a_{i}\right)$, say between 1000 and 3000 in this example. The law of large numbers indicates that for most $x$, the sum $\underline{x} \underline{x}$ will lie in this range.

## THE TRAPDOOR KNAPSACK

Shamir [43] has developed a different method of using the knapsack problem to obtain signatures.

## 6. Discussion

We have shown that it is possible to construct trap door. knapsack problems and that information and signatures can be hidden in them for transmission over an insecure channel. Conventional cryptographic systems also can hide information and authenticators during transaission over an insecure channel, but have the disadvantage that first a "key" must be exchanged via courier service or some other secure means. Also, in conventional cryptography, the authenticator only prevents third party forgeries and cannot be used to settle disputes between the transmitter and receiver as to whether a message was actually sent.

We have not proved that it is computationally difficult for an opponent who does not know the trap information to solve the problem. Indeed, proofs of security are not yet available for normal cryptographic systems, and even the general knapsack problem has not been proved difficult to solve. The theory of computational complexity has not yet reached the level of development where such proofs are feasible. The best published algorithm for solving the knapsack problem is exponential, taking $O\left(2^{n / 2}\right)$ time and space [10]. Schroeppel [33,unpublished] has devised an algorithm which takes $O\left(2^{n / 2}\right)$ time and $O\left(2^{n / 4}\right)$ space.

Faith in the security of these systems must therefore rest on intuition and on the failure of concerted attempts to break
them.
Attempts to break the system can start with simplified problems (e.g. assuming $m$ is known) (see chapter VII section 5.) If even the most favored of certificational attacks is unsuccessful, then there is a margin of safety against cleverer, wealthier, or luckier opponents. Or, if the favored attack is successful, it helps establish where the security really must reside.

As noted, the techniques suggested in this chapter generalize to $x_{i}$ in the set $\{0,1,2,3, \ldots, N\}$. The advantages and weaknesses of such systems deserve further study.

Recently, Rivest, Shamir, and Adleman [31] have proposed another public key cryptosystem, which yields signatures more directly because the density of solutions in their problem is 1. Their system also requires a smaller key (apparently 600 bits versus 20 kilobits); but is significantly slower. Neither system's security has been adequately established but, when iterated, the trap door knapsack appears less likely to possess a chink in its armor. When used for obtaining signatures, the trap door knapsack appears to be the weaker of the two. Both public key systems clearly need further certification and study.

## 7. Footnote

Other definitions of the knapsack problem exist in the literature [10], [11], [31]. The definition used here is adapted from Karp [13]. To be precise, Karp's knapsack problem is to determine whether or not a solution $\underline{x}$ exists, while the corresponding cryptographic problem is to determine what $x$ is, given that it exists. The cryptographic problem is not NPcomplete, but is just as hard as the corresponding NP-complete problem. If there is an algorithm for solving the cryptographic problem in time $T(n)$, i.e., for determining $\underline{x}$ given that it exists, then we can determine whether or not an $\underline{x}$ exists in time $T(n)$, i.e., solve the corresponding NP-complete problem. If the algorithm determines $\underline{x}$ in time $T(n)$, then some $\underline{x}$ exists. If the algorithm does not determine $\underline{x}$ in time $T(n)$, or determines an incorrect $\underline{x}$-which is easily checked-- then no such $\underline{x}$ exists.

## 1. Introduction

Although the knapsack problem can be used as the basis of a public key cryptosystem, a closer investigation of its security is needed in order to select the size and exact type of trapdoor knapsack to use. This chapter is a study of the knapsack problem from several perspectives, in an attempt to determine how secure it is, and what type of trapdoor knapsack is most suitable for actual implementation. Besides discussing the best known algorithos for solving the knapsack problem, and for solving special cases of the trapdoor knapsack problem, it also gives direct reductions of Boolean circuits to the knapsack problem. (The problem of Boolean circuits has already been shown to be NP-complete. As a byproduct of this reduction we show that if DES [24] is secure, so are general knapsacks with $n=10,000$.) The proofs presented are accessible to anyone with a modest knowledge of Boolean circuit theory, and require no theoretical background, (in particular, no knowledge of NP complete problems is assumed.). They can serve to demystify complexity theory as applied to the knapsack problem.

There are two aspects to the complexity of the knapsack problem. First, does there exist a method of solving the trapdoor knapsack which cannot solve the general knapsack problem? That is, is the trapdoor knapsack problem easy to solve even though the general knapsack problem is NP-complete and there-
fore presumably hard to solve? Secondly, what is the complexity of the general knapsack problem? Do there exist unusually efficient algorithms for solving the knapsack problem? Do there exist algorithms which will rapidly solve some knapsack problems? This chapter first attempts to give a better idea of the complexity of the general knapsack problem, both by considering the most efficient algorithms known for its solution, and by examining direct reductions of Boolean circuits to the knap sack problem. It will then examine some algorithms which can efficiently break certain specialized cases of the trapdoor knapsack problem.

## HOW SECURE IS THE TRAPDOOR KNAPSACK?

## 2. The Knapsack Problem

The knapsack problem is: given an integer $S$ and an integer vector $a=a_{1}, a_{2}, a_{3}, \ldots a_{n}$ find a vector $\underline{x}=x_{1}, x_{2}, \ldots x_{n}$ where $x_{i}$ is in $\{0,1\}$ such that $S=\underline{x}^{*}$ a, (where ${ }^{* n}$ denotes dot product.)

Karp [13] showed that this problem is NP-complete. The best published algorithm for solving this problem requires $2^{n / 2}$ operations and $2^{n / 2}$ memory [10]. This algorithm is simple in nature: all possible sums involving $a_{1}, a_{2}, \ldots a_{n / 2}$ are generated, and the list of $2^{\mathrm{n} / 2}$ possible sums is sorted. Then, all possible sums involving $a_{n / 2+1}, a_{n / 2+2}, \ldots a_{n}$ are generated, each sum is subtracted from $S$, and the resulting list of numbers is sorted. If a number in the first list matches a number in the second list, then a solution exists and can be readily computed. (An unpublished algorithm which runs in time $2^{n / 2}$ and in space $2^{n / 4}$ has been discovered by Schroeppel [33]).

The proof by Karp that this problem is NP-complete is elegant and concise, but gives little hint as to whether the best known algorithms (mentioned above) are very close to the best possible algorithms or whether much better algorithms are possible. A more fundamental problem with the use of the theory of NP complete problems is that the nondeterministic polynomial time Turing machine was reduced to the knapsack prob-
lem, but the actual complexity of a nondeterministic Turing machine has not been investigated closely enough for cryptographic purposes: in eryptography, constant factors are VERY. important.

Rather than reduce a non-deterministic Turing machine to the knapsack problem, it is more appropriate to reduce Boolean circuits to the knapsack problen. The rationale for this is simple: modern cryptographic systems are actually built out of Boolean circuits, 1.e., "and," "or" and "not" gates. Cryptographic systems built out of arbitrary combinations of such logical building blocks have already been certified. As a consequence, reducing Boolean circuits to the knspsack problem directly will not only let us infer that the knapsack problem is NP-complete, it will also let us draw some inferences about a lower bound on $n$ needed for a secure system. If it is possible to embed the problem of cryptanalyzing an already certified cryptographic system into a knapsack problem with $n=10,000$, then we can safely infer that there is no uniformly fast algorithm which can solve knapsack problems with $n=10,000$. Furthermore, the details of the actual reduction might give us some feel for the security of the knapsack problem.

We first extend the problem of Boolean circuits by including a multi-input multi-output "gate," which is intended to model the ROM-based S-boxes (substitution boxes) found in many modern cryptographic functions. We define a "(k,m)S-box" as a device with $k$ Boolean inputs, and m Boolean outputs, where the
function which determines the output from the input is arbitrary. As an example, figure 1 shows the truth table for a $(3,2)$ S-box.

| input | output |
| :---: | :---: |
| 000 | 01 |
| 001 | 11 |
| 010 | 00 |
| 011 | 10 |
| 100 | 11 |
| 101 | 11 |
| 110 | 01 |
| 111 | 00 |

Figure 1

The reader should notice that "and" and "or" gates are just (2,1)S-boxes, and a "not" gate is just a (1,1)S-box. These devices will therefore not be considered separately.

In order to embed a modern cryptographic function into the knapsack problem, it is sufficient if we cen embed arbitrary ( $k, m$ )S-boxes and their interconnections. This can be done easily, and the (3,2)S-box of figure 1 is shown in figure 2 embedded in a knapsack problem with $n=13$. The $\left\{a_{i}\right\}$ and $S$ have been chosen so that exactly $B \underline{x}$ vectors satisfy $S=\underline{a} \underline{x}$ and these 8 vectors specify the data of figure 1 under the follow-
ing interpretation.

$$
\begin{aligned}
& a_{1}=000-01 \ldots \\
& a_{2}=001-11 \ldots \\
& a_{3}=010-00 \\
& a_{4}=011-10 \ldots 1 \\
& a_{5}=100-11 \ldots \\
& a_{6}=101 \ldots 11 \\
& a_{7}=110 \ldots 01 \\
& a_{8}=111-00
\end{aligned}
$$

input $1 \quad a_{9}=100-00 \ldots-0$
input $2 \quad a_{10}=010-00 \ldots-\ldots 0$
input $3 \quad a_{11}=001-00 \ldots 0$
output $1 \quad a_{12}=000-10 \ldots-10$
output $2 \quad a_{13}=000-01 \ldots-0$
sum $s=111-11 \ldots-1$

Figure 2

The $a_{i}$ are shown in binary, and "-" is used for zero's which are not structurally important, but which are used only for spacing and to prevent carries between the three structural fields during addition of the $a_{i}, x_{9}, x_{10}$, and $x_{11}$ represent the 3 input values to the $S$-box in complementary notation. If
$x_{9}$ is 0 , then input 1 to the $S$-box is a 1 . If $x_{9}$ is a 1 , then input 1 is a 0 . Similarly for $x_{10}$ and $x_{11}$. The outputs are represented, again in complementary logic, by $x_{12}$ and $x_{13}$. The variables $x_{1}$. through $x_{g}$ are not interpreted, they are part of the "internal workings" of this S-box representation. The final "1" in $a_{1}$ through $a_{8}$ coupled with the requirement that $s$ end in 1 guarantees that oniy one of $x_{1}$ through $x_{8}$ can be a 1 , all the rest must be $0^{\prime} s$.

Perhaps the best explanation of this $S-b o x$ is to work through an example of what happens when a given 3-bit input is specified as part of the $x$ vector, and how it eventually produces the correct 2-bit output, al so as part of the $x$ vector.

Figure 1 shows that on input 110 this $S$-box must produce output 01. Input 110 corresponds to $x_{9}=0, x_{10}=0$, and $x_{11}=$ 1 , and output 01 corresponds to $x_{12}=1$ and $x_{13}=0$. To force $a_{7}$, which corresponds to this input-output pair, to be included in the sum we set the first three bits of $S$ to 111. Only one of $x_{1}$ through $x_{8}$ can be a 1 , and the $x_{i}$ selected must make the first 3 bits of the sum equal 111. Because carries are prevented between the three structural fields, the only possible choice is $x_{7}=1$, and the rest of $x_{1}$ through $x_{8}$ are equal to 0. Now, $x_{7}$ has a two-bit "output" section, which is the correct output (01) for the original input 110. By choosing the second field in $S$ to be 11 we force $x_{12}$ and $x_{13}$ to assume the correct output in complementary notation (10) in a manner analogous, but precisely reversed, from the manner in which the
input selected $x_{7}$ in the first place.
The reader should note that $a_{1}$ through $a_{8}$ in figure 2 are nearly exact copies of the $S$-box shown in figure 1 , the only change being the addition of structurally unimportant o's, indicated with "_". The last. structural field is the constant, 1. Each of, $a_{9}$ through $a_{11}$ has a single 1 bit, surrounded by 0 bits to form an "identity matrix" in the first structural field. The same is true for $a_{12}$ through $a_{13}$ in the second structural field.

The knapsack problem in figure 2 models the (3,2)S-box in figure 1, but the details of how to interconnect two or more S-boxes into a single circuit must still be developed. For simplicity, we do this with an example using two identical $S$ boxes. These can be represented by a single knapsack with $n=$ 26, and of twice the "width" as the original knapsacks with six structural fields. The first three fields are used only for $a_{1}$ to $a_{13}$ to represent the first S-box. The second three fields are only used for $a_{14}$ through $a_{26}$ to represent the second $S-$ box. By including a non-structural buffer of $0^{1} s$ between fields three and four, any $x$ vector which solves the knapsack problem is consistent with the input/output relation of both S-boxes. Figure 3 shows the result of applying this procedure to generate two non-interconnected S-boxes identical to the S box of figures 1 and 2 .

To interconnect an output from one $S$-box to an input of the other S-box, we must force the associated $x_{i}$ and $x_{j}$ to be
equal to each other. To connect input 1 of the first, $S$-box ( $a_{9}$ in figure 3) to output 2 of the second S-box ( $a_{26}$ in figure 3) we must force $x_{9}$ to equal $x_{26}$. This is done by making $x_{9}$ identical to $x_{26}$, i.e.. $a_{26}$ is removed, and a new $a_{9}^{\prime}$ is defined to be the sum of $a_{9}$ and $a_{26}$. This is illustrated in figure 4. In general, to connect $a_{i}$ with $a_{j}$, create $a_{j}=a_{j}+a_{i}$, and delete the old $a_{i}$.

As an example, if we wished to have two $(3,2)$ S.boxes exactly like the one shown in figures 1 and 2, and to interconnect the second output of one with the first input of the other, the result would look like figure 3.

| input |  |
| :---: | :---: |
| input 2 | $a_{23}^{22}=-\ldots-\ldots-1-010-00$ |
| input 3 |  |
| output 1 | $a_{25}=---$--------1000-10 |
| output 2 | $a_{26}=--3-1-000-01$ |

$s=111-11 \ldots-1111 \ldots-11$

Figure 4

From figure 2 it is seen that a ( $k, m$ ) $S-b o x$ can be imbedded in a kmapsack of size $2^{k}+k+m$. Outputs of one $S$-box will usualIy serve as inputs to other S-boxes, so the size of the knapsack which represents the interconnection of several s-boxes will be somewhat reduced from the sum of the sizes of the knapsacks representing the isolated $S$-boxes.

To model cryptanalysis, note that in a known plaintext attack, the key is the only free input to the circuit because the plaintext and ciphertext are fixed. (The known plaintext and ciphertext values can be obtained in the circuit by several methods, the easiest to explain is to use $(1,1)$ s-boxes whose outputs are independent of their inputs.) Any $\underline{x}$ vector which solves the resultant knapsack problem specifies the key in complementary notation. Solving the knapsack problem is thus at least as hard as eryptanalysis of the system modeled by the Boolean circuitry.

It is now possible to embed the problem of eryptanslysis of a modern encryption function into the knapsack directly. As an example we consider embedding the National Eureau of Standards Data Encryption Standard (DES) [24]. Although there is controversy about the security of the DES [5], [15], there is little doubt that an encryption function with an equivalent complexity could be made secure. Because the embedding we describe could be used to embed any encryption function of comparable complexity into the same size knapsack problem, the security of the DES is not an issue.

We shall not consider the DES algorithm in any great detail, except to estimate the number and type of s-boxes it contains. It has 8 s-boxes, but requires 16 "rounds" or iteram. tions. That is, the DES is a clocked sequential circuit which requires 16 clock periods to compute a result. Because we can model only combinatorial circuits, and not sequential circuits, we must "unroll" the 16 rounds into a single combinatorial circuit 16 times longer than the circuitry required for a single round. We shall therefore compute how large a knapsack would be required to model a single round of the DES algorithm, and then multiply by 16 .

There are $8(6,4)$ S-boxes involved in one round. In addition, there are $80(2,1)$ S-boxes used for exclusive-oring. of these, 48 are used to ex-or the key with the data, and 32 to ex-or the two halves of the data. The result is $8 \cdot\left(2^{6}+6+\right.$ $4)+80 \cdot\left(2^{2}+2+1\right)=1152$. To continue this for 16 rounds would require a knapsack with $n=18432$.

This estimate is conservative (too large) for two major reasons: First, the $(2,1) S-b o x e s$ are used for exclusive-or gates, and exclusive-or gates can in fact be implemented in a knapsack of size $n=4$, rather than $n=7$. Second, this counts the input of one S-box which is also the output of a preceding S-box twice, again inflating the size of knapsack needed. If both of these factors are taken into account, the size of the knapsack required shrinks to $n=11,264$. A few more improvements can yield an $n$ of about 10,000 , but further improvements
become more difficult at this point. We shall use the estimate $n=10,000$ for the rest of the chapter.

The interpretation given to this fact (that the DES can be. imbedded in a knapsack of size $n=10,000$ ) is quite straightforward: should an algorithm exist which can efficiently and uniformly solve knapsack problems with $n=10,000$, then the DES -and all other encryption functions of similar complexity- can be broken. Because the second statement is highly implausible, it is also highly implausible that any fast algorithm will be found for solving arbitrary knapsacks with $n=10,000$.

The best known algorithm for solving the knapsack problem, coupled with the largest computer that can be 1magined will be totally unable to solve knapsack problems with $\mathrm{n}=1000$. Even solution of knapsacks with $n=100$ will be prohibitively expensive with today's technology.

Even if we accept $n=100$ as a lower bound and $n=10,000$ as an upper bound on the size of knapsack problem necessary for a secure system, there is still a great deal of difference between the two. Fortunately, the upper bound seems very loose. A knapsack with $n=10,000$ can actually embed any DESlike encryption function with $16 \cdot 8=128$ ( 6,4 )S-boxes, as well as some auxiliary logic.

## 3. Double Sum is Easy to Solve

An apparently effective method for reducing the value of $n$ in the trapdoor knapsack (thus reducing the size of the public enciphering key a) is to allow the $x_{i}$ to take on values in the range $\{0,1,2, \ldots$ B instead of the range $\{0,1\}$. Starting with $n=100$ and $B=1$ (the usual case) and pushing this to its 1 1mit produces $n=1$ and $E=2^{100}-1$ with

$$
S=a_{1} \cdot x_{1}
$$

as the enciphering operation. Cryptanalysis is easily done by one division. The case $n=2$ results in the double sum problem defined as: given integers $S, a_{1}, a_{2}$, and $P$, find integers $x_{1}$ and $x_{2}$ such that

$$
\begin{align*}
S= & a_{1} \cdot x_{1}+a_{2} \cdot x_{2}  \tag{7.1}\\
& \text { and } \quad 0 \leq x_{1}, x_{2}<B \tag{7.2}
\end{align*}
$$

We may assume that $\operatorname{CCD}\left(a_{1}, a_{2}\right)=1$ since otherwise we can compute their GCD and divide $a_{1}, a_{2}$, and $S$ by it to get a new problem with $\operatorname{GCD}\left(a_{1}, a_{2}\right)=1$. Then we can use the GCD algorithm to generate numbers $y_{1}$ and $y_{2}$ such that

$$
1=a_{1} \cdot y_{1}+a_{2} \cdot y_{2}
$$

Multiplying this equation by $S$ gives

$$
s=a_{1} \cdot\left(s \cdot y_{1}\right)+a_{2} \cdot\left(s \cdot y_{2}\right)
$$

We also have

## HOW SECURE IS THE TRAPDOOR KNAPSACK?

$$
0=a_{1} \cdot a_{2}+a_{2} \cdot\left(-a_{1}\right)
$$

If we add multiples of the second equation to the first, we will still have an equation which satisfies (7.1), and because $a_{1}$ and $a_{2}$ are relatively prime, it generates all possible solutions to (7.1).

The solution must satisfy (7.1), and $X_{1}$ can be expressed in the form

$$
\begin{equation*}
x_{1}=k \cdot a_{2}+r \tag{7.3}
\end{equation*}
$$

which gives

$$
\begin{equation*}
S=a_{1} \cdot\left(k \cdot \ddot{a}_{2}+r\right)+a_{2} \cdot x_{2} \tag{7.4}
\end{equation*}
$$

Furthermore, the value of $r$ can be computed from

$$
S \cdot y_{1}=x_{1}=k \cdot a_{2}+r \bmod a_{2}
$$

or

$$
s \cdot y_{1}=r \bmod a_{2}
$$

We must satisfy $x_{1}<$ E. We must also satisfy (7.1) and $^{\text {(7. }}$ (7.2), which implies $x_{1}<(S+1) / a_{1}$. If $x_{1} \geq(S+1) / a_{1}$, then $x_{2}$ $<0$, contradicting (7.2). If we let min $=\min \left(B,(S+1) / a, a_{1}\right)$ then these two conditions reduce to $x_{1}<m i n$. If we now select the largest allowable value of $\mathrm{x}_{\mathrm{g}}$, which will generate the smallest possible value of $x_{2}$, either it is a solution, or no solution exists. Using equation (7.3), we heve

$$
k \cdot a_{2}+r=x_{1}<\min
$$

or

$$
k \cdot a_{2}<\min -r
$$

or

## HOW SECURE IS THE TRAPDOOR KNAPSACK?

$$
k<(\min -r) / a_{2}
$$

so the largest allowable value of k will be

$$
k=(\min -r-1) / a_{2}
$$

By truncating $k$ to an integer, we obtain an exact solution to (7.3), and generate a value for $x_{1}$.

We now compute $x_{2}$, using the already obtained value of $x_{1}$, and determine if $x_{2}<B$. If $x_{2}<B$, we have computed the solution. Otherwise, no solution exists.

To summarize: $\quad 1=a_{1} \cdot y_{1}+a_{2} \cdot y_{2}$ compute $r=S \cdot y_{1} \bmod a_{2}$ compute min $=\min \left(b,(S+1) / a_{1}\right)$ compute $k=(\min -r-1) / a_{2}$ if $k<0$, there is no solution truncate $k$ compute $x_{1}=k \cdot a_{2}+r$ compute $x_{2}=\left(S-a_{1} \cdot x_{1}\right) / a_{2}$ if $x_{2}<B$ then $x$ is the solution otherwise no solution exists

It is clear that $n=2$ is not safe, At the present time, although we do not have a fully tested general algorithm. for solving problems with $n=3$, the author believes that this is also not safe. It is not clear whether $n=4$ is safe, but small values of $n$, i.e., less than 10 , should certainly be avoided at the present time. The author wishes to emphasize that estimates about a "safen value of $n$ have a large subjective component. The only method of establishing that a particular selection of parameters for the trapdoor knapsack can be relied on to provide a high level of security is to have a certificational attack on the system by individuals skilled in cryptanalysis and the particular problem area. Closer investigation of the parameter $n$ in the generalized knapsack seems justified before adopting a value for a particular system. (Certificational attacks should optimally include the creators of the system as one group. Those interested in initiating a serious certification of the trapdoor knapsack should contact the author.)
5. How Nany Iterations of the Knapsack is Safe?

Although even the single iteration knapsack has not yet been broken, it is the author's bellef that at least two or three iterations of the ( $w, m$ ) transform are needed to produce a margin of safety. The author would presently feel comfortable with ten iterations, although, as mentioned before, such "feelings" should be viewed with caution. A full certificational attack by several experts would be preferable.

Work by the author, by Martin Hellman, and by Adi Shamir [umpublished] on the security of the single iteration trapdoor knapsack indicates that revealing any one of the parameters allows solution of the problem.

Taking the three cases in order, let us assume that in addition to the public vector $\mathfrak{a}$, our opponent learns a'in a single iteration trapdoor knapsack. In this case, the following equations hold:

$$
\begin{array}{ll}
a_{1} \cdot w=a_{1}^{\prime} & \bmod m \\
a_{2} \cdot w=a_{2}^{\prime} & \bmod m
\end{array}
$$

Which in turn implies that

$$
a_{1} \cdot w \cdot a_{2}^{1}=a_{2} \cdot w \cdot a_{1}^{\prime} \bmod m
$$

which together with $\operatorname{GCD}(w, m)=1$ implies

$$
a_{1} \cdot a_{2}^{1}-a_{2} \cdot a_{1}^{i}=k \cdot m
$$

where $k$ is an unknown integer.
The essential point of this computation is that we can easily compute a multiple of $m$. By repeating this trick a few times with other numbers from the trapdoor knapsack, we can compute several different multiples of $m$. Taking their ged will then give us $m$, which can in turn be used to recover w. If all we know. is m , we can often recover w using a method devised by Shamir [42]. The basic equations behind this method are:

$$
\begin{aligned}
& a_{1} \cdot w=a_{1}^{\prime} \bmod m \\
& a_{2} \cdot w=a_{2}^{1} \bmod m
\end{aligned}
$$

which implies

$$
a_{1} / a_{2}=a_{j}^{\prime} / a_{2}^{\prime} \quad \bmod m
$$

But we can compute $a_{1} / a_{2}$ mod $m$, which lets us rewrite the equation as:

$$
\text { known }=a_{1}^{\prime} / a_{2}^{1}
$$

$$
a_{2}^{\prime} \cdot k n o w n=a_{1}^{\prime} \bmod m
$$

Furthermore, we know that $a_{1}^{\prime}$ and $a_{2}^{\prime}$ are very small compared with $m$. We therefore seek two numbers satisfying
$n_{1} \cdot$ known $=n_{2} \quad$ mod $m$
$n_{1}, n_{2}$ are small
and hope that these two numbers are $\varepsilon_{1}^{\prime}$ and $a_{2}^{\prime}$ (Shamir [42] has the details). In many cases, our hopes will be satisfied. In particular, random function arguments imply that the solution will be unique if length $\left(a_{1}^{\prime}\right)+\operatorname{length}\left(a_{2}^{1}\right)<$ length $(m)$. Although it is fairly easy to pick $m$ small enough to foil this particular attack, it still indicates that $m$ should be kept secret to maintain security. Although m might not satisfy the constraint given, it might still be possible to solve for $a_{1}^{1}$ and $a ;$ using a generalized attack with the first three elements of the trapdoor knapsack:

Finally, if $\mathrm{w}^{-1}$ is known, this allows ready computation of $w^{-1} \cdot a_{1}, w^{-1} \cdot a_{2}$ and $w^{-1} \cdot a_{3}$. These numbers are all equal to a multiple of $m$ plus the small numbers (relative to $m$ ) $a_{p}^{1}$. $a_{2}^{\prime}$ and $a_{3}^{\prime}$ All we need do is compute a number which satisfies these conditions, and we have recovered $m$.

Since there are three secret parameters in the single

HOW SECURE IS THE TRAPDOOR KNAPSACK?
Iteration trapdoor knapsack and making any one pubiic destroys security, conservatism dictates using the iterated trapdoor knapsadk even though all three parameters are secret. Much as product ciphers can build a strong encryption function by iterating weak simple ciphers, so the iterated trapdoor knapsack builds, strength by iterating the ( $w, m$ ) transform.

## 6. Conclusion

#### Abstract

The purpose of this chapter has been to give the reader a better idea of the security of particular trapdoor knapsack problems. It seems clear at this time that a trapdoor knepsack with $n=1000$, with 100 iterations, and with each number in the a vector 5000 bits long should be totally secure, Reducing these numbers to more practical values is essential before the trapdoor knapsack is used in a real system.

VIII. AN NP-COMPLETE CONVENTIONAL CIPHER

## 1. Introduction

It is possible to make a conventional cipher based on the knapsack problem which is essentially NP-complete, Those knowledgeable about the theory of NP-completeness might object to the use of the term "NP-complete" in these circumstances, so the qualification ${ }^{n}$ essentially" has been added. The precise distinctions are more definitional than substantive and are explained below.

It appears that the proof technique used here can be generalized to other ciphers.

## 2. The Easic Idea

It is possible to create a one way function based on the knapsack problem by defining $\underline{x}$ to be the input to the function, $S$ to be the output from the function, and $a=a_{1}, a_{2}, \ldots a_{n}$ as the function specification. This allows definition of the function by

$$
F(\underline{x})=S=\underline{x}^{*} \underline{a}
$$

(where * denotes dot product).
We can define a stream cipher [4] based on this:

$$
C_{t}=P_{t} \otimes F\left(\underline{x}_{t}\right.
$$

and the deciphering process is just:

$$
P_{t}=C_{t} \oplus F\left(\underline{x}_{t}\right.
$$

where 9 represents modulo two addition (exclusive or), $\underline{x}$ is defined to be the key and $P_{t}, C_{t}$, and $F(\underline{x})_{t}$ are all one bit quantities. $\quad C_{t}$ is the single bit of ciphertext transmitted at time $t$; $P_{t}$ is the single bit of plaintext generated by $A$ at time $t ;$ and $F(\underline{x})_{t}$ is the single bit of $S$ needed to encrypt $P_{t}$ at time t.

The advantage of this definition is that the key, $x$, is the argiment of a one way function, and should therefore be difficult to determine.

To be useful, it must be possible to send indefinite amounts of plaintext: $P$ must be infinite. This implies $S$ must be infinite. This in turn implies that the $a_{i}$ must be infinite. (Notice that it does not imply $x$ is infinite.) Infinite $a_{i}$ 's are trivial: they need only be generated as indefinite streams, least significant bit first. For each index i in $\{1,2, \ldots n\}, A$ will transmit $a_{i, 1}, a_{i, 2}, \ldots a_{1, t} \ldots$ At time $t, A$ will transmit $n+1$ bits: $a_{1, t}{ }^{a_{2, t}}{ }^{\prime} a_{3, t} \ldots a_{n, t}{ }^{\prime}$ and $C_{t}$.

A uses key $\underline{x}$ to select a subset of the $a_{1}$. A adds up the subset of the $a_{i}$ to compute the sum, $S$. $B$ knows $x$, hence $A$ can also compute $S$. (Everyone knows $\mathfrak{a}$, which is public knowledge.)

Because the $a_{j}$ are infinite in length, $S$ will also be infinite in length. As the $a_{i}$ are transmitted, least significant bit first, it will become possible for $B$ to compute $S$, also least significant bit first. That is, $S$ will be a bit stream, computable from the $n$ bit streams $a_{1}, a_{2}, \ldots a_{n}$, and the key X.

```
time t: ... 987654321
```

```
    a}=\mp@code{l
    a
    •
    •
    an
    S = ...0010100101011001
    P=_... 11 1 1 00001 1 1 1.000
    C = .... 1 0 1 000100100001
```

Figure 1

E cannot learn $\underline{x}$ without solving the knapsack problem but it seems conceivable that E might be able to deduce some portion of $S$ without ever knowing $x$. In the following paragraphs, this is shown to be impossible.

If we assume E attacks this cipher under a known plaintext attack, then $E$ knows $S_{t}$ for $t \leq$ the present time. This is because

$$
S_{t}=P_{t} \oplus C_{t}
$$

In spite of this, $E$ will not be able to compute $S_{t}$ for any $t>$. the present time, even given the full values of the $a_{i}$ (which extend indefinitely into the future) without also solving for $x$, and thus solving the knapsack problem. This can be proven by contradiction.

Assume $E$ can predict $S_{t}$ for some $t \geqslant$ the present time and for any value of the $a_{i}$. To determine if $x_{i}$ is a or a $1, E$ makes two predictions. $E$ first predicts $S_{t}$, and then makes another prediction $\hat{S}_{t}$ after complementing the single bit, $a_{i, t}$. If $\hat{S}_{t} \neq S_{t}$, then $x_{i}$ must be a 1 , otherwise it must be a 0.

This proves that solving this cipher for even one bit of unknown plaintext allows $E$ to recover one of the $x_{i}$. Repeating this $n$ times allows recovery of the $x$ vector, thus solving the knapsack problem.

Why is this cipher only "essentially" NP-complete? In essence, the question is the distinction between the following two problems:

Find $x$, given that we know it exists.
Determine whether or not $x$ exists.
The latter is the knapsack problem, and is NP-complete. The former is not quite the knapsack problem, and $I$ have been calling it "essentially" NP-complete.

Fron a cryptographer's point of view there is not much difference between these two problems. If an algorithm exists
that will find $\underline{x}$ in time $T(n)$, then we can determine whether or not $\underline{x}$ exists by running the algorithn for time $T(n)$ and noting whether it produces the correct $\underline{x}$ at the end of that time. If it does produce the correct, $\underline{x}$, then $\underline{x}$ exists. If it did not find any $\underline{x}$ in that time, no $\underline{x}$ exists.

It con be argued that this "proof" is inadequate because we have not taken into account the time required to compute $T$ itself. It is not the purpose of this chapter to provide airtight theoretical definitions, simply to point out that such theoretical considerations exist, but do not appear to be im--"
portant for cryptographic applications.

## AN NP-COMPLETE CONVENTIONAL CIPHER

3. Conclusion

A conventional cipher which is essentially NP-complete was given. This cipher, based on the knapsack problem, is the first with this property known to the author.

## IX. PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

1. Introduction

This chapter examines the ways in which public key systems can be used and the special strengths they offer, by giving a series of example protocols. Beyond providing recipes for solving some specific problems, these examples are intended to improve the reader's ability to judge other protocols and, when faced with new problems, to synthesize new protocols.

The reader is assumed to be familiar with the general ideas bebind public key cryptosystems, as described in [6], [4].

For many of the following examples, we shall need the services of two communicants, called $A$ and $E$, and an opponent $E$. $A$ and $E$ will attempt to send secret messeges and sign contracts, while $E$ will attempt to discover the keys, learn the secrets, and forge contracts. Sometimes, A will attempt to evade a contract he signed with $E$, or $E$ will attempt to forge A's signature to a new contract.

A and $B$ will need to apply one way functions to various arguments of various sizes, so we define the one way function $F$ Hith the properties that:

1) F can be applied to any argument of any size. $F$ applied to more than one argument is defined to be the same as $F$ applied to the concatenation of the arguments.
2) F will produce an output of fixed size (perhaps 100 bits)
3) Given $F$ and $x$ it is easy to compute $F(x)$.
4) Given $\bar{F}$ and $F(x)$ it must be impossible to determine $x$.
5) Given $F$ and $x$, it must be impossible to determine $x^{\prime}$ $\neq x$ such that $F(x)=F\left(x^{\prime}\right)$.

For a more complete discussion of one way functions, see [7], [38], [19] and chapter II.

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

## 2. Centralized Key Distribution

Centralized key distribution using conventional encryption functions was the only reasonabie method of handing key distribution in a multi-user environment before the discovery of public key distribution methods. Only conventional encryption functions need be used, which presently offers a performance advantage. (The currently known public key systems are less efficient than conventional cryptographic systems. Whether or not this will continue is not now known. Discovery of new public key systems seems almost inevitable, and discovery of more efficient ones probable.)

In centralized key distribution, $A, B$, and all other system users somehow deposit a conventional cryptographic key with a central key distribution center. Call $X$ 's key ${ }^{\prime}$, and let. $C($ key, plaintext) be the ciphertext resulting from the conventional encryption function. If A wishes to communicate with E , then $A$ picks a random key $k^{\prime}$ and computes $y=C\left(k_{A},<k^{\prime}\right.$, "send this key to $\mathbb{E}^{\prime \prime}>$ ) and sends it to the center along with his name. The center computes $C^{-1}\left(k_{A}, y\right)=\left\langle k^{\prime},{ }^{n}\right.$ send this key to $\left.B^{\prime \prime}\right\rangle$ and then computes $z=C\left(k_{B},\left\langle k^{\prime}\right.\right.$,"this key is from $\left.\left.A^{\prime \prime}\right\rangle\right)$ and sends this to $E$. $B$ computes $C^{-1}\left(k_{R}, z\right)=\left\langle k^{\prime}\right.$, "this key is from $A^{\text {n }}$ ) and uses $k^{\prime}$ in further encrypted communications with $A$.

This protocol is simple and requires only conventional encryption functions. Needham and Schroeder [25] and Popek and

Kline [27] have defended its use.

The major vulnerability of this protocol is to both centralized loss of security and centralized loss of function. All of the eggs are in a central basket. Theft of the central keys, or bribery of personnel at the central site will compromise all users of the system. Similarly, destruction of the central keys destroys the key distribution mechanism for all users. In addition, even though $A$ and $B$ can communicate with each other, if either of them is unable to communjcate with the key distribution center they will not be able to establish a secure key. In contrast, public key distribution will be seen to continue to function when only two users are left, and only the single communication path between them is functional. Public key systems are much more robust.

The security and reliability of centralized key distribution can be increased by using two or more centers, each with its own keys [6]: Destruction or compromise of a single center will not affect the other center. If users always use several keys --one from each center-m both to encrypt and decrypt messages, then compromise of a single key (or a single center) has no effect on user security. Only if all centers are compromised is the users' security compromised. In general, any number of centers can be established; although practical considerations will usually dictate a small number, e.g., two to five.

A system with multiple centers forces each user to estab-
lish a key with each center. This increases cost, but also increases security. There are two ways of modeling this increase in security. In the first, we argue thet the probability of compronising one center is $p$. so the probability of compromising $k$ centers is $p^{k}$. If $p$ is reasonably small, this model predicts a rapid and dramatic increase in security as the number of centers is increased. In the second model we argue that if the cost of compromising one center is d dollars, then the cost of compromising $k$ centers is only $k \cdot d$ dollars. This model predicts only a- small increase in security as new centers are added. The truth probably lies somewhere in between.

The centralized key distribution protocol does not fully solve the key distribution problem. Some sort of key distribution method must be used between each user $X$ and the center to establish each $\mathrm{k}_{\mathrm{X}}$. This problem is nontrivial because no electronic communications can be used for the transmission of $k_{X}$, and inexpensive physical methods, e.g., registered mail, offer only moderate security. The use of couriers is reasonably secure, although more expensive. Some implementations of public key distribution protocols do not require a secure channel for transmitting individual keys, rather they only require authentication of one (system) key or the root node in a tree authentication system (see sections 5 and 6).

Centralized key distribution is more vulnerable to both loss of security and loss of function than well designed public key distribution systems. At the present time, it does provide

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

improved performance because conventional encryption functions are more efficient (faster or require less memory) than pubiic key functions, In addition, certified conventional encryption functions are widely available, but this is not true of public key systems. The latter two situations can be expected to change.
3. Simple Public Key Distribution

This is the most basic application of public key systems [6], [18], [20], [21], [31]. Its purpose is to allow A and B to agree on a common key $k$ without any prior secret arrangements, even though $E$ overhears all messages. While public key distribution systems which are not based on public key cryptosystems exist [6], [20], we describe the protocol in terms of a public key cryptosysten. A randomly computes enciphering and deciphering keys $E_{A}$ and $D_{A}$, and sends $E_{A}$ to $B$ (and inadvertently $E$ ). B picks a random key, $k$, and transmits $E_{A}(k)$ to $A$ (and E). A computes $D_{A}\left(E_{A}(k)\right)=k$. A then discards both $E_{A}$ and $D_{A}$, and $B$ discards $E_{A}$. The key in future commications is $k$. It is used to encrypt all further messages using a conventional encryption function. Once $A$ and $E$ have finished talking, they both discard $k$. If they later resume the conversation the process is repeated to agree on a new key k'.

This protocol is very simple, and has a great deal to recommend it. First, no keys and no secret materials exist before $A$ and $B$ start communicating, and nothing is retained after they have finished. It is impossible for $E$ to compromise any keys either before the conversation takes place, or after it is over, for the keys exist only during the conversation. Furthermore, if $E$ is passive and does not actively interfere with the ressages being sent, then $E$ will understand nothing and the

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

conversation will be secure.

The disadvantage of this protocol is that Emight actively interfere with the exchange of keys. Worse yet, if $E$ has control of the channel, he can force a known $k$ on both $A$ and $E$. All further messages encrypted with $k$ can then be read by $E$. All $E$ need do is pretend to $E$ that be is $A$, and pretend to $A$ that he is $E$. To do this, $E$ blocks transmission of $E_{A}$ to $E$, and substitutes $E_{E} \cdot B$ will compute $E_{E}(k)$ and transmit it to $A$. E will block this transmission, learn $k$ by computing $D_{E}\left(E_{E}(k)\right)$ $=k$ and then send $E_{A}(k)$ to $A$. A will compute $D_{A}\left(E_{A}(k)\right)=k$ as usual. E knows $\bar{k}$, and both $A$ and $B$ are none the wiser.

In spite of this disadvantage, the protocol is very useful for two reasons. Passive eavesdropping, by itself, is a major problem. In "The Codebreakers," the authoritative 1164 page history of cryptography by David Kahn [12], the threat was from passive eavesoropping in the vast majority of cases. Use of a simple public key distribution protocol provides protection from this attack, and also provides a positive guarantee against lost or stolen codebooks, bribery or blackmail of codeclerks, and "practical cryptanalysis" by theft of keys. For example, the major vulnerability of the U.S. telephone network today is from technically sophisticated passive eavesdropping. The Russians use their embassies and consulates in the U.S. to house microwave receivers which listen to conversations carried between telephone company microwave towers [36], [3]. They are not jamming or altering phone calls; just listening.

## PROTOCOLS FOR PURLIC KEY CRYPTOSYSTEMS

#### Abstract

Secondly, if the reader has a preference for any other key distribution protocol which does not provide these blanket guarantees against lost or stolen keys, then it is simple to. combine the readers preferred key distribution protocol with the simple public key distribution protocol to obtain a hybrid which offers the strengths of both. The problem of carelessly lost keys, poor key security, theft of keys, and bribery of clerks or janitors who have access to the key are not minor, as history shows [12]. A blanket guarantee against all passive attacks is extremely comforting.

When guarantees of authenticity are also required, the simple public key distribution protocol can be used together with other methods because of the remarkably strong guarantees it provides against the passive eavesdropper. Even though a "better" method is being used to provide authenticity, its security might have been compromised by theft of keys, in which case it is impossible to guarantee authenticity, but the simple key distribution protocol at least still guarantees secrecy.

## PROTOCCLS FOR PUBLIC KEY CRYPTOSYSTEHS

## 4. Authenticated Public Key Distribution

There is a now classic protocol [6] which provides secure and authenticated communications between $A$ and $B: A$ and $B$ generate $F_{A}$ and $E_{B}$ and make them public, while keeping $D_{A}$ and $D_{B}$ secret. The public enciphering keys of all users are entered in a public file, allowing easy and authenticated access to $E_{X}$ for any user, $X$. $E_{X}$ can be authenticated upon entry in the file by $X$ making a personal appearance.

If $A$ and $B$ wish to agree on a common key $k$, then

1) A looks up $E_{B}$ in the public file.
2) A generates $k_{1}$ randomly and transmits $E_{R}\left(k_{1}\right)$ to $B$.
3) $B$ looks up $E_{A}$ in the public file.
4) E generates $k_{2}$ randomly and transmits $E_{A}\left(k_{2}\right)$ to $A$.
5) A computes $k=\left\langle k_{1}, k_{2}\right\rangle$, where $k_{2}=D_{A}\left(E_{A}\left(k_{2}\right)\right)$.
6) $B$ computes $k=\left\langle k_{1}, k_{2}\right\rangle$, where $k_{1}=D_{B}\left(E_{B}\left(k_{1}\right)\right)$.

At the end of this protocol, $A$ and $P$ have agreed on a common key, $k$, which is both secret and authenticated. $A$ is assured he is talking to $B$, for only $E$ can decipher $E_{B}\left(k_{1}\right)$, while $B$ is assured he is talking to $A$ because only $A$ can decipher $E_{A}\left(k_{2}\right)$.

This protocol suffers from two weaknesses. First, entries in the public file might be altered. E might create a false
entry in $A^{\top} s$ public file which read:

$$
\text { B................E } E_{E}
$$

This false entry would let $E$ pretend to $A$ that he was $B$, to the disadvantage of both $A$ and $P_{\text {. }}$

False entries in the public file can be dealt with both by good physical security, or by using new protocols (see sections 5 and 6) for authenticating the entries in the public file.

Second, secret deciphering keys can be lost. If $E$ should learn $D_{R}$, then $\bar{E}$ could masquerade as $E$ to $A$ without altering the public file. Unless additional precautions are taken, A and $B$ might never find out about the loss. Note that if $D_{B}$ is compromised but $D_{A}$ is still secure, then $A$ can no longer be sure he is talking to $B$, but he can be sure he is talking secretly to some (umauthenticated) person claiming to be $B$.

## 5. Public Key Distribution with Certificates

Kohnfelder [14] suggested that entries in the public file can be authenticated by having a Central Authority (CA) sign them with $D_{C A}$. He called such signed entries certificates. The certificate for $A$, called $C_{A}$, is computed by the central authority as:

$$
C_{A}=D_{C A}\left(\left\langle\text { "user } A^{n}, E_{A}\right\rangle\right)
$$

while similarly $\mathrm{C}_{\mathrm{B}}$ is computed as:

$$
C_{B}=D_{C A}\left(\left\langle\text { user } B^{n}, E_{B}\right\rangle\right)
$$

The protocol with certificates is the same as the authenticated protocol, except steps 1 and 3 , which involve looking $\operatorname{up} E_{A}$ and $E_{B}$, are replaced by the steps of obtaining and checking the certificates for $A$ and $B$. The modified protocol is:

1) A obtains $\mathrm{E}^{1} \mathrm{~s}$ certificate (either from a public file, or by requesting it from $B$ ) and confirms it by computing

$$
E_{C A}\left(C_{B}\right)=\text { "user } P \text { " }, E_{B}
$$

2) A generates $k_{1}$ randomly and transmits $E_{E}\left(k_{1}\right)$ to $B$.
3) B obtains $A^{\prime} s$ certificate and confirms it by computing

$$
E_{C A}\left(C_{A}\right)=\text { "user } A^{\prime \prime}, E_{A}
$$

4) E generates $k_{2}$ randomly and transmits $E_{A}\left(k_{2}\right)$ to $A$.
5) A computes $k=\left\langle k_{1}, k_{2}\right\rangle$, where $k_{2}=D_{A}\left(E_{A}\left(k_{2}\right)\right)$.
6) $E$ computes $k=\left\langle k_{1}, k_{2}\right\rangle$, where $k_{1}=D_{B}\left(E_{P}\left(k_{1}\right)\right)$.

This protocol assures $A$ and $P$ that each has the other's public enciphering key, and not the public enciphering key of some imposter.

The security of this protocol rests on the assumptions that $D_{A}, D_{B}$, and $D_{C A}$ have not been compromised, that $A$ and $E$ have correct copies of $E_{C A}$, and that the central authority has not issued a bad certificate, either deliberately because it was untrustworthy, or accidentelly because it was tricked.
$E_{C A}$ can be published in newspapers and magazines, and sent over all available communication channels. Blocking its correct reception would be very difficult.

Security can be improved by having several "Central Authorities," each with its own secret deciphering key. Each user would be given a certificate from each authority, all authenticating the same public enciphering key. Compromise of a single authority will no longer result in compromise of the system.

If only a single "Central Authority" exists, and $D_{C A}$ is compronised, then it is no longer possible to authenticate the users of the system and their public enciphering keys. The certificates are now worthless because the (unauthorized) person who has learned $D_{C A}$ can produce false certificates at will.

## PROTOCOLS FOR PURLIC KEY CRYPTOSYSTEMS

#### Abstract

This problem can be greatly reduced by destroying $D_{C A}$ after certificates for all users have been oreated. If $D_{C A}$ no longer exists, it cannot be compromised. The central authority would create $E_{C A}$ and $D_{C A}$, sign all the certificates, then immediately destroy $\mathrm{D}_{\mathrm{CA}}$. $\mathrm{D}_{\mathrm{CA}}$ would be vulnerable only during the short time that it was being used to sign certificates.

While it is now impossible for anyone to falsely add new users to the system by creating false certificates, it is also impossible to add legitimate users to the system as well. This is unacceptable. The simplest way of dealing with this problem is for the central authority to issue new certificates with a new (different) secret deciphering key. For example, each month the central authority could create new certificates for that month's new users using a newly created $D_{C A}$. The new $E_{C A}$ would be published, and the new users would be accepted. The new $D_{C A}$ would be destroyed after use.

Although this method sharply reduces the risk that $D_{C A}$ might be compromised, it still leaves open the possibility that the central authority might issue bad certificates either by intent, or because of some trickery during the short period when new certificates are actually being signed. These possibilities can be effectively eliminated by the next protocol.

## 6. Public Key Distribution with Tree Authentication

Key distribution with certificates was vulnerable to the criticism that $D_{C A}$ can be compromised, resulting in system wide loss of authentication (elthough not necessarily loss of secrecy). This problem can be solved by using tree authentication, as described in Chapter $V$.

Again, this protocol attempts to authenticate entries in the public file. However, instead of signing each entry in the public file, this protocol applies a one way hash function, $H$. to the entire pubiic file. Even though H is applied to the entire public file, the output of H is only 100 or 200 bits 20 ng . The (small) output of $H$ will be called the root, $R$, of the public file. If all users of the system know $R$, then all users can authenticate the correctness of the (whole) public file by computing $\mathrm{R}=\mathrm{H}$ (public file). Any attempt to introduce changes into the public file will imply with probability near one that $R \neq H(a l t e r e d ~ p u b l i c ~ f i l e), ~ a n ~ e a s i l y ~ d e t e c t e d ~ f a c t . ~$

This method efrectively eliminates the possibility of compromising $D_{C A}$ because no secret deciphering key exists. Anyone can compute $R=H$ (public file), and so confirm that the copy of the public file that they have is correct. $R$, (like $\mathrm{E}_{\mathrm{CA}}$ in the protocol of section 5) can be widely distributed.

Because correct copies of the public file are widely distributed, it is very easy for a user of the system to discover
that someone else is attempting to masquerade as him. If E has put the false entry
A............... $E_{E}$
into the public file, then $A$ will discover this fact when he looks at his own entry. A cannot be given a specially "printed" public file with his entry correct because then $H$ (public file) would not equal $R$. If new public files are issued before they go into use, then all users of the system will bave time to assure that they have been correctly entered into the public file. Because the public file will be subjected to the harsh glare of public scrutiny, and because meking alterations in the public file is effectively impossible, a high degree of assurance that the public file is correct can be attained.

While this concept is very comforting, forcing each user to keep a complete copy of the public file might not be practical. Fortunately, it is possible to selectively authenticate individual entries in the public file, without having to know the whole public file. This is done by using "tree authentication," described in chapter $V$.

The essence of tree authentication is to authenticate the entire public file by "divide and conquer." If we define $\underline{Y}=$ public file $=Y_{1}, Y_{2}, \ldots Y_{n}$, (so the ith entry in the public file is denoted $Y_{i}$, and $F^{\prime} s$ entry is $Y_{B}$; we can define H(public file) $=H(\underline{Y})$ as:

$$
H(\underline{Y})=F(H(f i r s t ~ h a l f \text { of } \underline{Y}), H(\text { second hal } f \text { of } \underline{Y}))
$$

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

Where $F$ is a one way function defined in section 1.
If A wishes to confirm B's public enciphering key, then A need only know the first half of the public file, (which is where $Y_{B}$ appears) and $H$ (second half of public file) which is only 100 bits long. A can compute $\mathrm{H}(\mathrm{public}$ file) knowing only this information, and yet $A$ only knows half the entries in the public file.

In a similar fashion, A does not really need to know all of the first half of the public file, for

```
H(first half of public file) =
    F( H(first quarter of public file),
    H(second quarter of public file) )
```

All A needs to know is the first quarter of the public file (which has $Y_{B}$ ), and $H$ (second quarter of public file).

By applying this concept recursively, A can confirm $Y_{F}$ in the public file knowing only $\mathrm{R}, \log _{2} \mathrm{n}$ intermediate H values, and $Y_{B}$ itself. The information needed to authenticate $Y_{B}$, given that $R$ has already been authenticated, lies along the path from $R$ to $Y_{B}$. This information will be called the authentication path.

These definitions are illustrated in figure 1, which shows the authentication path for $Y_{5}$.

This brief sketch of tree authentication should serve to convey the idea. For a more detailed discussion the reader is

Page 123B
referred to chapter $V$.
Using tree authentication, user $A$ has an authentication path which can be used to authenticate user A's public enciphering key, provided that $R$ has already been authenticated. An "authentication path" is a new form of certificate, with $E_{C A}$ replaced by R .

The advantage of tree authentication over certificates is that no secret deciphering key $D_{C A}$ exists, so $D_{C A}$ cannot be compromised. It is impossible to create false certificates after $R$ is computed.

With tree authentication, it is impossible to have a centralized loss of authentication, but it is also impossible to add new. users without issuing a new tree. The tree, once computed, is fixed and unchanging. Therefore, the public file (winich is just the leaves of the tree) is also fixed and unchanging. For this reason, it can be carefully and publicly checked for errors. For the same reason, it is impossible to update. A new tree must be issued periodically.

In summary: If tree authentication is used to authenticate each entry in the public file, the protocol for public key distribution proceeds as follows:

1) A obtains $\mathrm{B}^{\prime}$ s entry in the public file and B's authentication path (either from P or from some convenient storage device) and confirms their correctness.
2) A generates $k_{1}$ randomly and transmits $E_{B}\left(k_{1}\right)$ to $B$.

PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEME
3) B obtains A's entry in the public file and A's authentication path and confirms their correctness.
4) $E$ generates $k_{2}$ randomly and transmits $E_{A}\left(k_{2}\right)$ to $A$.
5) A computes $k=\left\langle k_{1}, k_{2}\right\rangle$, where $k_{2}=D_{A}\left(E_{A}\left(k_{2}\right)\right)$.
6) $B$ computes $k=\left\langle k_{1}, k_{2}\right\rangle$, where $k_{1}=D_{P}\left(E_{B}\left(k_{1}\right)\right)$.

This protocol can only be compromised if: $D_{A}$ or $D_{B}$ is compromised, or if $R$ is not correctly known by $A$ or $B$, or if there is a false and misleading entry in the public file. The latter two are easily detectable. If either $A$ or $B$ has the wrong $R$, they will be unable to complete the protocol with any other legitimate user who has the correct $R$. Complete failure of the protocol is easily detected, and will lead to some sort of corrective action. Implicitly, the correct value of $R$ is agreed on by $A$ and $B$ every time each confirms the correctness of the other's authentication path. The correct value of $R$ is therefore being constantly transmitted between pairs of users as they establish keys. This is in addition to other means of confirming $R$, such as publication.

Because the public file is both open to public scrutiny and unalterable, false or misleading entries can be rapidly detected. In practice, a few users concerned with correctness can verify that the public file satisfies some simple global properties, i.e., each user name appears once and only once in the entire public file; individual users can then verify that

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

their own entry is correct, and need not bother examining the rest of the public file.

The only practical method of compromising either A's or $B^{\prime}$ s security is to compromise $D_{A}$ or $D_{B}$. $A$ user's security is thus dependent on himself and no one else.

It is still possible for $A$ to claim to be the non-existent C. Because $C$ does not exist, he will never object that $A$ is masquerading as him. A can effectively establish pseudonyms. If it is essential to establish a one to one correspondence between named users of the system and real people, some form of physical authentication is necessary. In many applications there is no need to know that user $C$ is really a pseudonym for user A. As long as $C$ pays his bills, his real identity is irrelevant. The identifier " C " is relative, not absolute, and serves simply to tie together a sequence of transactions.

## 7. Digital Signatures

Diffie and Hellman [6] suggested the use of public key cryptosystems to provide digital signatures, and Rivest, Shamir and Adleman [31] have suggested an attractive implementation. Signature techniques based on methods other than public key cryptosystems have been suggested by Lamport and Diffie [6], Rabin [29], and Merkle [19].

Digital signatures, whether based on conventional encryption functions, on public key cryptosystems, on probabilistic computations, or on other techniques, share several important properties in common. These common properties are best illustrated by explaining the general concept of a digital signature.

The now classic example of a digital signature is that of a person A who wishes to place a purchase order with his stock broker $P$. A has just received word that the stock will go up in value, and wishes to purchase it within a few hours. $A$, on the Riviera, cannot send a written order to B in New York in time. All that $A$ can quickly send to $P$ is information, i.e., a sequence of bits, but $B$ is concerned that $A$ may later disclaim the order. A must somehow generate a sequence of bits (a digital signature) which will convince $E$ (and if need be, a judge) that $A$ authorized the order. It must be easy for $P$ to validate the digital signature, but impossible for him (or anyone other
than $A$ ) to generate it (to prevent charges that $B$ was dabbling in the market illegally with A's money).

The signature must be a function of both the message and. the signer, for it must convince $B$ (and a judge) that the particular person, A, has signed the particular message, m. There is basically one situation which the digital signature must resolve: B claims that A signed a message, and A claims be did not. If in fact $A$ signed the message, then he is guilty of disavowal; but if he did not. $B$ is guilty of forgery. To summarize: a digital signature should be message dependent, signer dependent, easy for the sender to generate, easy for the user to validate, but impossible to forge or disavow.

There are digital signature schemes which do not involve public key cryptosystems, and some which involveelaborate interactions between $A$ and $E$, as well as the clever use of random information [29], but it will be convenient notationally to let A sign message $m$ by computing the signature, $D_{A}(m)$. Checking a signature will then be done by checking that $m=E_{A}\left(D_{A}(m)\right)$. If $E_{A}\left(D_{A}(m)\right.$ ) produces an illegible message (random bits) then the signature is rejected as invalid. This notation is somewhat misleading because the actual method of generating and validating signatures can be very different from this model. This notation is retained because it is widely known and because we will not discuss the differences among different digital signeture methods, only their common properties. The conclusions reached in the following paragraphs apply to both public key

## PROTOCOLS FOR PURLIC KEY CRYPTOSYSTEMS

and non-public key based signature systems.

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

## 8. A Simple Digital Signature Protocol

The first digital signature protocol, proposed in [6], proceeded as follows:
$A$ and $B$ agree on message $m$ that $A$ is to sign. A computes $D_{A}(m)$ (where $D_{A}$ is known only to $A$ ) and transmits it to $B . B$ looks up $E_{A}$ in the public file. B can now check $D_{A}(m)$ by computing $E_{A}\left(D_{A}(m)\right)$ and confirming that it equals $m$. $B$ retains $D_{A}(m)$ as proof that $A$ signed message $m$.

If $A$ later denies having signed message $m, ~ P$ can give $D_{A}(m)$ to a judge, who can easily compute $E_{A}\left(D_{A}(m)\right)=m$, proving that A signed the message.

This protocol has been criticized [32], [27] on two grounds.

First, the public file might have been tampered with. When $B$ looks up $E_{A}$ in the public file, E might have altered the public file so that $E_{E}$ appears next to $A$ 's name. $B$ will then "check" a signature with the wrong public enciphering key, making E's "check" useless. Methods of authenticating the public file, discussed previously under key distribution protocols, minimize this problem.

A second criticism, raised by Saltzer [32] and by Popek and Kline [27], is that $A$ can disavow the signed message, explaining " $E$ has stolen $D_{A}$, and has posted it in a public place. Clearly, anyone could have computed $D_{A}(m)$, so it proves nothing." In fact, $E$ did not steal anything; $A$ posted $D_{A}$ in a pub-
lic place himself. A can now disavow any message he ever signed.

Although this simple protocol is flawed, it should be com-. pared with current practice. At the moment, it is possible to order goods and services simply by giving a valid credit card number and nothing else.

Further, A cannot disavow a signed message without generating suspicion. Repeated disavowals would be especially questioned. In an. actual system, the incidence of disavowal will be low, which implies that careful investigation of those cases that do occur is possible.

A simple solution to the disavowal problem is to adopt very good physical security for $D_{A}$, and then refuse to accept $A^{\prime}$ s claim that $D_{A}$ was compromised. Several factors combine to allow extraordinarily good physical security for $D_{A}$ First, destruction of $D_{A}$ is merely inconvenient. $A$ can always generate a new $D^{\prime} A_{A}$ and $E_{A}^{\prime}$. If theft of $D_{A}$ is imminent, $A$ can destroy $D_{A}$. Contracts signed with $D_{A}$ are still valid and $E_{A}$ still exists to authenticate them, even though $D_{A}$ has been destroyed.

Second, only a single copy of $D_{A}$ need exist. Because destruction of $D_{A}$ is only inconvenient, backup coples of $D_{A}$ need not be kept. $D_{A}$ could be kept in a small strong box or on a single chip of silicon in a "signet ring" worn by A. Attempts to open the ring would cause destruction of $D_{A}$.

To summarize, the simple signature protocol is a great im-
provement. over the current situation (no signature protocol), but it suffers from three problems: the public file that $B$ checks must be accurate; $A$ might disavow the resulting signa-. ture, explaining (falsely) that $D_{A}$ was stolen; and $D_{A}$ might actually be stolen by $E$ who can then impersonate $A$. Authenticating the entries in the public file was considered under public key distribution protocols. Physical security of $D_{A}$ is.A's responsibility. Disavowal is considered further in section 9.

## 9. Dealing with Disavowal

If it is necessary to assume that $D_{A}$ can be compromised, then several protocols which reduce or mitigate the problem of disavowal suggest themselves.

One solution is to have a witness testify to the time of the order only. Essentially, this reduces the role of the witness to that of a reliable time stamp. As mentioned before, if a message was signed prior to the time the key was compromised, then it must be valid. The witness signs a statement of the format "The time is now 12:04:23 on the 17th of March, 1979, and I have been presented with the following bit pattern xxxxxxyxxxxyxxxxxyxxx." If the witness' signature is still valid, and the witness signed the statement prior to the time $D_{A}$ was compromised, then the witnessed signature must also be valid. The witness need not physically authenticate A's agreement; the witness does not care where the bit pattern comes from nor what it means.

If A claims he lost $D_{A}$ yesterday, then a message signed three months ago and "time stamped" by a witness two months ago is still valid. Only A's recently signed messages are open to question.

A can still disavow a message signed at $2: 00$ explaining that his signature was compromised at $1: 00$ but that he didn't notice this fact until $3: 00$. If $A$ 's argument that $D_{A}$ was
compronised and he failed to notice this for two hours is accepted, then he can disavow a signed message. Since the "benefit" of most disavowals (e.g. stock orders) is not realized un-. til a significent time after the message is sent, time stamping is more valuable than might first appear.

If there is a witness who is trusted not to disavow his signature, why not rely on him entirely, and eliminate $A^{\prime} s$ digital signature completely? The witness' testimony that A agreed to the contract would $B E$ the "signature." If the witness is fully trusted, he need not even use digital signatures. He could simply remember the contracts. In the event of dispute, the witness would simply look up the appropriate contract, and all parties to the dispute would abide by that version. (Popek and Kline [27] advocate the use of such methods.)

The primary disadvantage to this alternative is that $A$ loses control over his signing ability. The witness can now forge A's "signature" on a contract, either because the witness is malicious, or because the witness made a mistake. If the witness' word is accepted as binding, $A$ would have no recourse. Even though a swore that he had not seen the contract, had not agreed to the contract, and would never have agreed to the contract, if the "signature" provided by the witness is to be useful, A's pleas must be ignored. In contrast, if the witness only countersigns $A^{\prime} s$ digital signature, then $A$ is guaranteed that forgery is impossible so long as $D_{A}$ is secure. In addition, if $A$ is in San Francisco, $B$ is in New York,
and the witness is in Philadelphia, then some form of seeure commanications between the various sites is required. This adds additional points of vulnerability to the system.

Finally, if the witness is responsible for many contracts worth many millions of dollars, it is an attractive target for system penetrators and vandals. Ey contrast, digital signatures are distributed; there is no central site whose destruction or compromise would invalidate all signatures for all users.

Disavowal is an inherent property.of any signature technique, including written signatures, stamps, seals, etc. For any signature system, the signer can try to disavow his signature by creating a fanciful but not impossible scenario which would have allowed someone else to have forged the signature. The essential question is the plausibility of these scenarios. As their plausibility is reduced, the risk of disavowal is also reduced. To be practical, a signature system must reduce the risk of disavowal to a level which is tolerable for the particular application. Complete elimination of all risk does not appear to be attainable.in practice.

## PROTOCOLS FOR PUBLIC KEY CRYPTOSYSTEMS

10. Conclusions
The primary purpose of this chapter has been to increase the readers insight into the strengths and weaknesses not only of the particular protocols described, but also of cryptographic protocols in general. Certainly, these are not the only cryptographic protocols possible. However, these protocols are valuable tools to the system designer: they illustrate what can be achieved and provide feasible solutions to some problems of recurring interest.

Diffie and Hellman [5] have argued that the 56 -bit key used in the Federal Data Encryption Standard (DES) [24] is too small and that current technology allows an exhaustive search of the $2^{56}$ keys. Although there is controversy surrounding this issue $[9,15,34,23,40,2]$, there is almost universal agreement $[37,5]$ that multiple encryption using independent keys can increase the strength of DES. But, as noted in [5], the increase in security can be far less than might first appear. This chapter shows that a recently proposed scheme [37] for multiple encryption suffers from such a weakness.

The simplest approach to increasing the key size is to encrypt twice, with two independent keys $K 1$ and $K 2$. Letting $P$ be a 64 bit plaintext, $C$ a 64 bit ciphertext, and $K$ a 56 bit key, the basic DES encryption operation can be represented as

$$
\begin{equation*}
c=s_{K}(P) \tag{i0.1}
\end{equation*}
$$

and simple double encryption is obtained as

$$
\begin{equation*}
C=S_{K 2}\left[S_{K 1}(P)\right] \tag{10.2}
\end{equation*}
$$

While exhaustive search over all $2^{112}$ keys ( (K1,K2) pairs) requires $?^{112}$ operations and is clearly infeasible, this cipiner can be broken under a known plaintext attack (where corresponding pleintext and ciphertext are both know) with $2^{56}$ operations [5], and $2^{56}$ words of memory. The complexity, meas-
ured as time plus memory is therefore no greater than is needed to cryptanalyze a single 56 bit key exhaustively. (Though the cost is somewhat higher since memory is "more expensive" than time.) If $P$ and $C$ represent a known plaintext-ciphertext pair, then the algorithm for accomplishing this [5] encrypts $P$ under all $2^{56}$ possible values of K1, decrypts $C$ under all $2^{56}$ values of K 2 and looks for a match. For obvious reasons this is called a "meet in the middle" attack and is given in detai]. by the following algorithm (Where $n$ is the number of keys in the key space. For DES, $n=2^{56}$ ):

```
1.) 5or i = 1 to n Do
    a.) Tobie"i] = \langleS (P),i,"encrypt"\rangle
    b.) Table[n+i] = <S [i (C), i,"decrypt">
2.) Sort the table on the first field.
3.) Search the table for adjacent entries of the form
    <value,K1,"encrypt">
    <value,\hat{K2,"decrypt">}
        and test to see if \hat{K1}}\mathrm{ and }\hat{K}2\mathrm{ are the correct keys by
        encrypting further plaintext-ciphertext pairs. Based
        cn unicity distance arguments [30,35], there will be
        about 2 [8 "false alarms" for F\hat{F}
        plaintext-ciphertext pair is used. Testing these
        tekes less than 2 26}\mathrm{ operations and therefore contri-
        butes an unimportant overhead to the computetion.
```

While the algorithm given runs in time $n$ log $n$, it could be rewritten using hash tables to run in essentially linear time. In any event, the present analysis will neglect logarithmic factors.
The use of double encryption provides some increase in security because the algorithm for cryptanalysis requires $2^{56}$ words of memory, as well as $2^{56}$ operations. The cost of a machine to perform $2^{56}$ operations in approximately a day has been estimated by Diffie and Hellman [5] to be about 20 million dollars. The cost of $2^{56} 64$-bit words of memory on 6250 cpi reels of mánetic tape, assuming 2400 foot reels that cost $\$ 15$ dollars eack, is about 60 billion dollars.
While the cost of implementing this searci is high enough to discourage its use today, the denger of cheaper technology or shortcuts [O] in the future prompted Difrie and Heliman to suggest triple encryption with three independent keys K1, K2 and K3. A generalized meet in the middle attack would then require $2^{112}$ operetions and be well beyond the foreseeable technology for at least 50 years, and possibly forever.
At the 1978 National Computer Conference, Tuchmen [37] proposed a triple encryption method which uses only two keys K1 and K2. The plėatext is encrypted with K1, decrypted with K2, then again encrypted with K1 so that:

$$
\begin{equation*}
\tau=S_{K 1}\left\{S_{K 2}^{-1}\left[S_{K 1}(P)\right]\right\} \tag{10.3}
\end{equation*}
$$

This method seems to avoid the "meet in the middle" attack outlined above and is upwardly compatible with a single encryption by setting K ? $=\mathrm{K} 2$ to produce:

$$
C=S_{K 1}\left\{S_{K 1}^{-1}\left[S_{K 1}(P)\right]\right\}=S_{K 1}(P) \quad \text { (10.4) }
$$

This allows users of the new (two key) system to decrypt data encrypted by users of the old (single key) system.

Although th: encryption technique (10.3) provides more security than simple double encryption as in (10.2), it is shown below thet the new method can be cryptanalyzed using a chosen pleintext attack [6] in about $\varepsilon^{56}$ operations. We therefore recommend that if triple encryption is used, there be three independent keys. If competibility with single enerypむion is desired, the operation can be taken to be:

$$
\begin{equation*}
C=S_{K 1}\left\{S_{K 2}^{-1}\left[S_{K 2}(P)\right]\right\} \tag{10.5}
\end{equation*}
$$

Then wher $K ?=K 2=K 3=K, C=S_{K}(P)$. Users could also be compatible with Tuchmen's suggested two key method by taking K1 = K3.

Althougt chosen pleintext attacks can sometimes be mounted on real systers, the following should be viewed as a "certificational attack" whioh is only indicative of $a$ weakness. History, littered with the broken remains of "unbreakable" ciphers, teaches extreme caution in certirying a new one [12], so that today even an indication of weakness is regarded as dangerous. In many cases, ciphers which have yielded to chosen
plaintext attacks have later proven vulnerable to known plaintext or ciphertext only attacks as well.

We define some useful notation before describing the method of eryptanalysis:

$$
\begin{align*}
C & =\operatorname{Enc}(P)=S_{K 1}\left\{S_{K 2}^{-1}\left[S_{K 1}(P)\right]\right\}  \tag{10.6}\\
M 1 & =S_{K 1}(P)  \tag{10.7}\\
M 2 & =S_{K 2}^{-1}(M 1)  \tag{10.8}\\
& =S_{K 2}^{-1}\left(S_{K 1}(P)\right)  \tag{10.9}\\
& =S_{K 1}^{-1}(C) \tag{10.10}
\end{align*}
$$

M1 and $N 2$ are intermediate values in the computation of $C$ from P.

We can motivate the method of cryptanalysis with the following observations:

If we know $K 1$ and a ( $P, C$ ) pair, then it would be possible to compute tine intermediate values $M 1$ and $N 2$ from (10.7) and (10.1C). This would let us mount a know pleintext attack on K2 using (10. \&). There are $2^{56}$ values of K 1 , so if we could quickly determine the right $K 2$ once we round the right $K 1$, then cryptenalysis would only take $2^{56}$ operations. Determining K 2 using a knomt plaintext attack requires $2^{56}$ operations, which is too lone.

The trick is to somehow change the known pieintext attack on K .2 to a crosen pleintext attack (that is, M. 1 is chosen in (10.2); for example, $M 1=\underline{0}$ ), so we can quickly solve for K 2
with a table lookup. This increases the memory needed to $2^{56}$ words, the same as is needeo by the meet in the middle attack for simple double encryption.

For this attack to work, we must find the value of $P$ such that $M_{1}=S_{K 1}(P)=0$. If we knew the right $K 1$, then we could easily compute $P=S_{K i}^{-1}(\underline{0})$ from(10.7), and eryptanalyze the syster. in one step, because we could then request Enc $(P)=C$, (by the chosen plaintext assumption) ; compute $s_{K 1}^{-1}(C)=M 2$; and con:pute $K 2$ in one step from N 2 using the precomputed table.

Since we do not know $K 1$, we repeat this process for each of its $2^{56}$ possible values and test any resulting (K1,K2) pairs to see whicr one is correct. Again using unicity distance arguments, we expect $2^{48}$ false alarms, which is small compared hith $2^{56}$.

Eecause $P=S_{K 1}^{-1}(\underline{0})$ fron (10.7) and $M 2=S_{K i}^{-1}(\underline{0})$ from (10.8) the algorithm can proceed as follows:
1.) For $i=1$ to $n$ Do
E.) $\hat{M 2}=s_{i}^{-1}(\underline{0})$
b.) Table[i] $=\langle\hat{N} 2, i$, "2">
c.) $\hat{N} 2=S_{i}^{-1}\left(\operatorname{Enc}\left(S_{i}^{-1}(\underline{0})\right)\right)$
c.) Table $[n+i]=\langle M 2, i, " 1 "\rangle$
2.) Sort the table on the first field.
3.) Search the table for adjacent entries or the form〈value, K2,"2"〉 <value, $\hat{K} 1, " 1 "\rangle$

## ON THE SECURITY OF MULTIPLE ENCRYPTION

and test to see if $K 1$ and $K 2$ are the correct keys bychecking further plaintext-ciphertext pairs.
Step 3 is guaranteed to find the correct (K1,K2) pair.

## Conclusion

Two methods of multiple encryption have been shown to be less secure than they first appeared. The weakness in both cases came from an ability to separate the key into two halves which did not interact. We conclude that all bits of the key should come into play repeatedly in a complex fashion as they do in the 56-bit DES, and that multiple encryption with any cryptographic system is liable to be much less secure than a syste- designed originally for the longer key.
The use of cryptography is growing because of the increasing demand for privecy as reflected in new legislation, the need to protect vulnerable electronic funds transfer systems, the increasing quantity and value of information sent over vulnerable communication channels, the dropping price of eavesdropping and analyzing information, and the dropping price of protecting information via encryption.
Although it is difficult to predict the curves and swerves of $a$ new and rapidly developing technology, it appears that many of the techniques described in this thesis will be used in telecommnication systems that span the globe to protect the privacy and integrity of communcations of all kinds.

## /*

General Comments:

The following routines have been written in $E C$, a simplified version of $C$ that does indefinite precision integer arithmetic. $B C$ runs on a PDP-11 under the Unix operating system.

BC has a few peculiar conventions as follows:
\% The infix mod operator. wim computes $w$ modulo m.
auto A local variable declaration.
++ The únary increment-by-one operator. As a postfix operator, it first returns the value of a variable, then increments 1t. As a prefix operator, it increments a variable and returns the incremented value.

- Same as ++, only it decrements.
!= The relational not-equal operator. $0!=1$ is true, but $0!=0$ is false.
$==\quad$ The relational equal operator: $0=0$ is true.
"..." The indicated string is printed, no print or output statement is needed.
$\exp$ A naked expression is printed. The statement
" $i=7$ ii
when $i$ has value 845 will print
$i=845$
To prevent unwanted printout of integer values from function calls, the construct

$$
f=f(a, b, c)
$$

will often appear, where $f$ is a dummy variable which is discarded
[] Left and right braces cannot appear in comments or in quotes (a bug) so all comments and quotes use. ( and ) for array subseripts.
; • The semicolon is optional at the end of a line. if $(0=0)$ statement; The statement is executed. This redundant construct is required because of bugs in BC .

This file contains all routines necessary to generate trapdoor knapsacks. EXCEPT the routine $r(l, h)$, used to generate a random number in the range from $l$ (low) to $h$ (high). That is, $r(1, h)$ is a random number satisfying

$$
1 \leq r(1, h) \leq n
$$

The main routine is m:make. Once called, it calls upon other routines, as needed, to generate the trapdoor knapsack.
*/
define m(m,n,r,g,b)\{
auto i,e,t
/* m:make makes the enciphering and deciphering keys for the iterated generalized knapsack method.

The input parameters have the following meanings:
$m:$ The size in bits of $m(1)$, the first modulus.
$n$ : The number of integers in the generalized

\section*{XIV. EXAMPLES OF TRAPDOOR KNAPSACKS}

\section*{1. Introduction}

This appendix gives some example trapdoor knapsacks. The author has retained the secret deciphering keys, and the reader Is challenged to break any of them. They are of marginal strength to encourage attempts to break them. Full documentation, including listings of all relevant programs and the enciphering key, are given.

\section*{2. Description}

The reader is assumed to be familiar with [6]. Most of the notation and all of the concepts that follow are described there.

The program which generates trapdoor kmapsack vectors has five input parameters, as well as a source of random integers. The random numbers are provided by a subroutine. This subroutine, \(r(1, h)\), accepts two arguments: a-lower limit and an upper Iimit. It returns a random integer in the range from the lower limit to the upper limit (inclusive).

The five parameters describe:
1) \(n\) : The number of integers in the knapsack.
2) \(b\) : The range of the \(x[i] .0 \leq x[i]<b\).
3) \(r\) : The number of iterations.
4) g: The "growth" of the \(m\) vector per iteration in bits.
(That 1s, m[i] is about \(2^{B} \cdot m[i-1]\) ).
5) \(m:\) The size of \(m[1]\), the first modulus. (Note that \(m\), as used in this context, is NOT the same as \(m\) described in [1]. The \(\underline{m}\) vector is the natural general1zation of \(m\) in [1].)

The reader can check his understanding of the parameters \(n, b\), and \(r\) by examining the following program segment. If we let the \(a^{\prime}\) vector be the easy to solve (secret) knapsack vector, and a be the publicly known knapsack vector, then the routine for decoding \(s\), the weighted sum of the integers in the \(a\) vector (s = \(\underline{x} \operatorname{dot} \underline{a}\) ) is:

For \(j=r\) downto 1 do \(s=s^{*} w[j] \bmod m[j]\);
For \(\mathrm{j}=\mathrm{n}\) downto 1 do
Begin
\(x[j]=s / a^{\prime}[j] ;\)
if( \(x[j]>=b\) ) print(" Error: \(x[j]\) larger than \(b ")\);
\(s=s-x[j] * a^{\prime}[j] ;\)
End

Note that the first For statement converts \(s\) from the difficult to solve knapsack problem to the easy to solve knapsack problem. The vectors \(w\) and \(m\) are just the generalizations of

\section*{EXAMPLES OF TRAPDOOR KNAPSACKS}
the integers \(w\) and \(m\) used in the single iteration knapsack. The second For statement decodes \(s\) into a weighted sum of the \(a^{\prime}[1]\).
- The parameters \(g\) and \(m\) are used to define the size of the integers.in the knapsack problem. In particular, m gives the size in bits of m[1], while g gives the "growth rate", i.e., the increase in the size between \(m[i]\) and \(m[i+1]\). These two parameters, taken together, define the size of m[i] for all \(i\). Knapsacks with the following parameters have been generated:
\begin{tabular}{lllll}
\(m\) & \(n\) & \(r\) & \(g\) & \(b\) \\
300 & 20 & 6 & 30 & \(2^{\wedge} 10\) \\
300 & 6 & 2 & 30 & \(2^{\wedge} 30\) \\
300 & 20 & 1 & - & \(2^{\wedge} 10\) \\
550 & 4 & 1 & - & \(2^{\wedge} 100\)
\end{tabular}

\section*{3. THE PUELIC ENCIPHERING KEYS}

The following section has the output of the trapdoor knap-. sack generating function. The output has been edited both for clarity and to delete the secret deciphering keys. The digits in the secret deciphering keys have been replaced with \(X^{1} s\), thus clearly showing the size of these numbers but concealing their exact values.

Numbers which require more than one line are extended using "\" at the eñ of the line.
